Recurrent Neural Networks

Single RNN cell

Unrolled RNN cells
Given an input $x(t)$ and previous state $s^{(t-1)}$, the new state is computed as

$$s^{(t)} = f(s^{(t-1)}, x(t); \theta).$$

One of the simplest possibilities is

$$s^{(t)} = \tanh(Us^{(t-1)} + Vx(t) + b).$$
Basic RNN Cell

Basic RNN cells suffer a lot from vanishing/exploding gradients (the challenge of long-term dependencies).

If we simplify the recurrence of states to

\[ s(t) = Us(t-1), \]

we get

\[ s(t) = U^t s(0). \]

If \( U \) has eigenvalue decomposition of \( U = QΛQ^{-1} \), we get

\[ s(t) = QΛ^t Q^{-1} s(0). \]

The main problem is that the same function is iteratively applied many times.

Several more complex RNN cell variants have been proposed, which alleviate this issue to some degree, namely LSTM and GRU.
Later in Gers, Schmidhuber & Cummins (1999) a possibility to *forget* information from memory cell $c_t$ was added.

\[
\begin{align*}
i_t & \leftarrow \sigma(W^i x_t + V^i h_{t-1} + b^i) \\
f_t & \leftarrow \sigma(W^f x_t + V^f h_{t-1} + b^f) \\
o_t & \leftarrow \sigma(W^o x_t + V^o h_{t-1} + b^o) \\
c_t & \leftarrow f_t \cdot c_{t-1} + i_t \cdot \tanh(W^y x_t + V^y h_{t-1} + b^y) \\
h_t & \leftarrow o_t \cdot \tanh(c_t)
\end{align*}
\]

Gated Recurrent Unit

Gated recurrent unit (GRU) was proposed by Cho et al. (2014) as a simplification of LSTM. The main differences are

- no memory cell
- forgetting and updating tied together
Gated Recurrent Unit

\[
\begin{align*}
    r_t & \leftarrow \sigma(W^r x_t + V^r h_{t-1} + b^r) \\
    u_t & \leftarrow \sigma(W^u x_t + V^u h_{t-1} + b^u) \\
    \hat{h}_t & \leftarrow \tanh(W^h x_t + V^h (r_t \cdot h_{t-1}) + b^h) \\
    h_t & \leftarrow u_t \cdot h_{t-1} + (1 - u_t) \cdot \hat{h}_t
\end{align*}
\]
Gated Recurrent Unit

\[ z_t = \sigma (W_z \cdot [h_{t-1}, x_t]) \]
\[ r_t = \sigma (W_r \cdot [h_{t-1}, x_t]) \]
\[ \tilde{h}_t = \tanh (W \cdot [r_t \ast h_{t-1}, x_t]) \]
\[ h_t = (1 - z_t) \ast h_{t-1} + z_t \ast \tilde{h}_t \]
Highway Networks
Highway Networks

For input \( x \), fully connected layer computes

\[
y \leftarrow H(x, W_H).
\]

Highway networks add residual connection with gating:

\[
y \leftarrow H(x, W_H) \cdot T(x, W_T) + x \cdot (1 - T(x, W_T)).
\]

Usually, the gating is defined as

\[
T(x, W_T) \leftarrow \sigma(W_T x + b_T).
\]
Figure 1: Comparison of optimization of plain networks and highway networks of various depths. 

*Left:* The training curves for the best hyperparameter settings obtained for each network depth. 

*Right:* Mean performance of top 10 (out of 100) hyperparameter settings. Plain networks become much harder to optimize with increasing depth, while highway networks with up to 100 layers can still be optimized well. Best viewed on screen (larger version included in Supplementary Material).

Figure 4: Lesioned training set performance (y-axis) of the best 50-layer highway networks on MNIST (left) and CIFAR-100 (right), as a function of the lesioned layer (x-axis). Evaluated on the full training set while forcefully closing all the transform gates of a single layer at a time. The non-lesioned performance is indicated as a dashed line at the bottom.

Figure 4 of paper "Training Very Deep Networks", https://arxiv.org/abs/1507.06228.
Dropout

- Using dropout on hidden states interferes with long-term dependencies.
- However, using dropout on the inputs and outputs works well and is used frequently.
  - In case residual connections are present, the output dropout needs to be applied before adding the residual connection.
- Several techniques were designed to allow using dropout on hidden states.
  - Variational Dropout
  - Recurrent Dropout
  - Zoneout
Regularizing RNNs

Variational Dropout

Figure 1 of paper "A Theoretically Grounded Application of Dropout in Recurrent Neural Networks", https://arxiv.org/abs/1512.05287.pdf

Implemented in `tf.keras.layers.{RNN,LSTM,GRU}` using dropout and recurrent_dropout arguments (for dropping inputs and previous states, respectively).
Regularizing RNNs

**Recurrent Dropout**
Dropout only candidate states (i.e., values added to the memory cell in LSTM and previous state in GRU).

**Zoneout**
Randomly preserve hidden activations instead of dropping them.

**Batch Normalization**
Very fragile and sensitive to proper initialization (there were papers with negative results until people managed to make it work).
Layer Normalization

Much more stable than batch normalization.

Figure 2: Validation curves for the attentive reader model. BN results are taken from [Cooijmans et al., 2016].

Word Embeddings

One-hot encoding considers all words to be independent of each other. However, words are not independent – some are more similar than others. Ideally, we would like some kind of similarity in the space of the word representations.

**Distributed Representation**

The idea behind distributed representation is that objects can be represented using a set of common underlying factors. We therefore represent words as fixed-size *embeddings* into $\mathbb{R}^d$ space, with the vector elements playing role of the common underlying factors.
The word embedding layer is in fact just a fully connected layer on top of one-hot encoding. However, it is important that this layer is *shared* across the whole network.
Word Embeddings for Unknown Words

Recurrent Character-level WEs

Word Embeddings for Unknown Words

Convolutional Character-level WEs

Figure 1 of paper "Character-Aware Neural Language Models", https://arxiv.org/abs/1508.06615.
Character-level WE Implementation

Training
- Generate unique words per batch.
- Process the unique words in the batch.
- Copy the resulting embeddings suitably in the batch.

Inference
- We can cache character-level word embeddings during inference.
**Basic RNN Applications**

**Sequence Element Classification**

Use outputs for individual elements.

```
input 1  
  ↓    
  state
  ↓    
output 1
```

```
input 2  
  ↓    
  state
  ↓    
output 2
```

```
input 3  
  ↓    
  state
  ↓    
output 3
```

```
input 4  
  ↓    
  state
  ↓    
output 4
```

**Sequence Representation**

Use state after processing the whole sequence (alternatively, take output of the last element).

Structured Prediction
Structured Prediction

Consider generating a sequence of $y_1, \ldots, y_N \in Y^N$ given input $x_1, \ldots, x_N$.

Predicting each sequence element independently models the distribution $P(y_i | X)$.

However, there may be dependencies among the $y_i$ themselves, which is difficult to capture by independent element classification.
Let $G = (V, E)$ be a graph such that $Y$ is indexed by vertices of $G$. Then $(X, y)$ is a conditional Markov field, if the random variables $y$ conditioned on $X$ obey the Markov property with respect to the graph, i.e.,

$$P(y_i | X, y_j, i \neq j) = P(y_i | X, y_j \forall j : (i, j) \in E).$$

Usually we assume that dependencies of $y$, conditioned on $X$, form a chain.
Linear-Chain Conditional Random Fields (CRF)

Linear-chain Conditional Random Fields, usually abbreviated only to CRF, acts as an output layer. It can be considered an extension of a softmax – instead of a sequence of independent softmaxes, CRF is a sentence-level softmax, with additional weights for neighboring sequence elements.

\[
s(X, y; \theta, A) = \sum_{i=1}^{N} \left( A_{y_{i-1}, y_i} + f_\theta(y_i | X) \right)
\]

\[
p(y | X) = \text{softmax}_{z \in Y^N} \left(s(X, z)\right)_z
\]

\[
\log p(y | X) = s(X, y) - \text{logadd}_{z \in Y^N}(s(X, z))
\]
Computation
We can compute \( p(y|X) \) efficiently using dynamic programming. We denote \( \alpha_t(k) \) the logarithmic probability of all \( t \)-element sequences with the last label \( y \) being \( k \).

The core idea is the following:

\[
\begin{array}{c|c|c}
  & j & k \\
\hline
  t-1 & & \\
\end{array}
\]

\[
\alpha_t(k) = f_\theta(y_t = k|X) + \log\text{add}_{j \in Y}(\alpha_{t-1}(j) + A_{j,k}).
\]

For efficient implementation, we use the fact that

\[
\ln(a + b) = \ln a + \ln\left(1 + e^{\ln b - \ln a}\right).
\]
**Conditional Random Fields (CRF)**

**Inputs:** Network computing \( f_\theta(y_t = k | X) \), an unnormalized probability of output sequence element probability being \( k \) at time \( t \).

**Inputs:** Transition matrix \( A \in \mathbb{R}^{Y \times Y} \).

**Inputs:** Input sequence \( X \) of length \( N \), gold labeling \( y^g \in Y^N \).

**Outputs:** Value of \( \log p(y | X) \).

**Time Complexity:** \( O(N \cdot Y^2) \).

- For \( t = 1, \ldots, N \):
  - For \( k = 1, \ldots, Y \):
    - \( \alpha_t(k) \leftarrow f_\theta(y_t = k | X) \)
    - If \( t > 1 \):
      - For \( j = 1, \ldots, Y \):
        - \( \alpha_t(k) \leftarrow \text{logadd}(\alpha_t(k), \alpha_{t-1}(j) + A_{j,k}) \)
  - Return \( \sum_{t=1}^{N} f_\theta(y_t = y_t^g | X) + \sum_{t=2}^{N} A_{y_{t-1}^g, y_t^g} - \text{logadd}_{k=1}^{Y}(\alpha_N(k)) \)
Conditional Random Fields (CRF)

Decoding
We can perform optimal decoding, by using the same algorithm, only replacing $\log\text{add}$ with $\max$ and tracking where the maximum was attained.

Applications
CRF output layers are useful for span labeling tasks, like

- named entity recognition
- dialog slot filling
