Structured Prediction
Structured Prediction

Consider generating a sequence of $y_1, \ldots, y_N \in Y^N$ given input $x_1, \ldots, x_N$.

Predicting each sequence element independently models the distribution $P(y_i|X)$.

$$
x_1 \quad x_2 \quad x_3 \quad \cdots \quad x_N
\downarrow \quad \downarrow \quad \downarrow \quad \cdots \quad \downarrow
y_1 \quad y_2 \quad y_3 \quad \cdots \quad y_N
$$

However, there may be dependencies among the $y_i$ themselves, which is difficult to capture by independent element classification.
We might model the dependencies by assuming that the output sequence is a Markov chain, and model it as

\[ P(y_i | X, y_{i-1}) . \]

Each label would be predicted by a softmax from the hidden state and the previous label.

The decoding can be then performed by a dynamic programming algorithm.
Maximum Entropy Markov Models

However, MEMMs suffer from a so-called label bias problem. Because the probability is factorized, each $P(y_i | X, y_{i-1})$ is a distribution and must sum to one.

Imagine there was a label error during prediction. In the next step, the model might “realize” that the previous label has very low probability of being followed by any label – however, it cannot express this by setting the probability of all following labels to a low value, it has to “conserve the mass”.

CRF, CTC, CTCDecoding, Word2Vec, CLEs, Subword Embeddings
Conditional Random Fields

Let $G = (V, E)$ be a graph such that $y$ is indexed by vertices of $G$. Then $(X, y)$ is a **conditional random field**, if the random variables $y$ conditioned on $X$ obey the Markov property with respect to the graph, i.e.,

$$P(y_i|X, \{y_j : \forall j \neq i\}) = P(y_i|X, \{y_j : \forall j : (i, j) \in E\}).$$

In plain speech, if you consider probabilities conditional on $X$, all the dependencies among $y$ are captured by the edges of the graph $G$.

By the **fundamental theorem of random fields (the Hammersley–Clifford theorem)**, the density of a conditional random field can be factorized over the **cliques** (complete subgraphs) of the graph $G$:

$$P(y|X) = \prod_{\text{clique } C \text{ of } G} P(y_C|X).$$
Most often, we assume that dependencies of $y$, conditioned on $X$, form a chain.

Then the cliques are *nodes* and *edges*, and we can factorize the probability as:

$$P(y|X) \propto \exp \left( \sum_{i=1}^{N} \log P(y_i|X) + \sum_{i=2}^{N} \log P(y_i, y_{i-1}|X) \right).$$
Linear-Chain Conditional Random Fields (CRF)

Linear-chain Conditional Random Field, usually abbreviated only to CRF, acts as an output layer. It can be considered an extension of softmax – instead of a sequence of independent softmaxes, it is a sentence-level softmax, with additional weights for neighboring sequence elements.

We start by defining a score of a label sequence $y$ as

$$s(X, y; \theta, A) = f(y_1 | X; \theta) + \sum_{i=2}^{N} (A_{y_{i-1}, y_i} + f(y_i | X; \theta)),$$

and define the probability of a label sequence $y$ using softmax:

$$p(y | X) = \text{softmax}_{z \in Y^N} (s(X, z))_y.$$

For cross-entropy (and also to avoid underflow), we need the logarithm of the probability:

$$\log p(y | X) = s(X, y) - \text{logsumexp}_{z \in Y^N} (s(X, z)),$$

where

$$\text{logsumexp}_x (f(x)) = \log \left( \sum_x e^{f(x)} \right).$$
Linear-Chain Conditional Random Fields (CRF)

Computation
We can compute $p(y|X)$ efficiently using dynamic programming. We denote $\alpha_t(k)$ the logarithmic probability of all $t$-element sequences with the last label $y$ being $k$.

The core idea is the following:

$$
\alpha_t(k) = f(y_t = k|X; \theta) + \log\text{sumexp}_{j \in Y} (\alpha_{t-1}(j) + A_{j,k}).
$$

For efficient implementation, we use the fact that

$$
\log(a + b) = \log a + \log(1 + e^{\log b - \log a}), \text{ so } \\
\log\text{sumexp}_x (f(x)) = \max_x (f(x)) + \log(\sum_x e^{f(x) - \max_x(f(x))}).
$$
Conditional Random Fields (CRF)

**Inputs:** Network computing \( f(y_t = k | X; \theta) \), which is a logit (unnormalized log-probability) of output sequence label being \( k \) at time \( t \).

**Inputs:** Transition matrix \( A \in \mathbb{R}^{Y \times Y} \).

**Inputs:** Input sequence \( X \) of length \( N \), gold labeling \( g \in Y^N \).

**Outputs:** Value of \( \log p(g | X) \).

**Time Complexity:** \( \mathcal{O}(N \cdot Y^2) \).

- For \( t = 1, \ldots, N \):
  - For \( k = 1, \ldots, Y \):
    - \( \alpha_t(k) \leftarrow f(y_t = k | X; \theta) \)
    - If \( t > 1 \):
      - \( \alpha_t(k) \leftarrow \alpha_t(k) + \text{logsumexp}_{j=1}^{Y} (\alpha_{t-1}(j) + A_{j,k}) \)
  - Return \( \sum_{t=1}^{N} f(y_t = g_t | X; \theta) + \sum_{t=2}^{N} A_{g_{t-1},g_t} - \text{logsumexp}_{k=1}^{Y} (\alpha_N(k)) \)
**Decoding**

We can perform decoding optimally, by using the same algorithm, only replacing $\logsumexp$ with $\max$, and tracking where the maximum was attained.

**Applications**

The CRF output layer is useful for **span labeling** tasks, like

- named entity recognition,
- dialog slot filling.

It can be also useful for image segmentation.
Let us again consider generating a sequence of $y_1, \ldots, y_M$ given input $x_1, \ldots, x_N$, but this time $M \leq N$, and there is no explicit alignment of $x$ and $y$ in the gold data.
Connectionist Temporal Classification

We enlarge the set of the output labels by a – (blank), and perform a classification for every input element to produce an extended labeling (in contrast to the original regular labeling). We then post-process it by the following rules (denoted as $B$):

1. We collapse multiple neighboring occurrences of the same symbol into one.
2. We remove the blank –.

Because the explicit alignment of inputs and labels is not known, we consider all possible alignments.

Denoting the probability of label $l$ at time $t$ as $p^t_l$, we define

$$\alpha^t(s) \overset{\text{def}}{=} \sum_{\text{extended labelings } \pi: B(\pi_{1:t}) = y_{1:s}} \prod_{i=1}^{t} p^i_{\pi_i}.$$

CRF  CTC  CTCDecoding  Word2Vec  CLEs  Subword Embeddings
In CRF, we normalize the whole sentences, therefore we need to compute unnormalized probabilities for all the (exponentially many) sentences. Decoding can be performed optimally.

In CTC, we normalize per each label. However, because we do not have explicit alignment, we compute probability of a labeling by summing probabilities of (generally exponentially many) extended labelings.
Computation

When aligning an extended labeling to a regular one, we need to consider whether the extended labeling ends by a *blank* or not. We therefore define

\[
\alpha_-(s) \overset{\text{def}}{=} \sum_{\text{extended labelings } \pi:} \prod_{i=1}^{t} p^i_{\pi_i} \quad \text{and} \quad B(\pi_{1:t}) = y_{1:s}, \pi_t = -
\]

\[
\alpha_+(s) \overset{\text{def}}{=} \sum_{\text{extended labelings } \pi:} \prod_{i=1}^{t} p^i_{\pi_i} \quad \text{and} \quad B(\pi_{1:t}) = y_{1:s}, \pi_t \neq -
\]

and compute \( \alpha^t(s) = \alpha^t_-(s) + \alpha^t_+(s) \).
Connectionist Temporal Classification

Computation – Initialization

We initialize $\alpha^1$ as follows:

- $\alpha^-_1(0) \leftarrow p^1_-$
- $\alpha^1_*(1) \leftarrow p^1_{y_1}$
- all other $\alpha^1$ to zeros

Computation – Induction Step

We then proceed recurrently according to:

- $\alpha^-_t(s) \leftarrow p^t_-(\alpha^t_{s-1}(s) + \alpha^-_{s-1}(s))$

- $\alpha^t_*(s) \leftarrow \begin{cases} p^t_{y_s}(\alpha^t_{s-1}(s) + \alpha^-_{s-1}(s - 1) + \alpha^t_{s-1}(s - 1)), & \text{if } y_s \neq y_{s-1} \\ p^t_{y_s}(\alpha^t_{s-1}(s) + \alpha^-_{s-1}(s - 1) + \alpha^t_{s-1}(s - 1)), & \text{if } y_s = y_{s-1} \end{cases}$

We can write the update as $p^t_{y_s}(\alpha^t_{s-1}(s) + \alpha^-_{s-1}(s - 1) + [y_s \neq y_{s-1}] \cdot \alpha^t_{s-1}(s - 1))$. 

Figure 7.3 of “Supervised Sequence Labelling with Recurrent Neural Networks” dissertation by Alex Graves
CTC Decoding

Unlike CRF, nobody knows how to perform decoding optimally in polynomial time. The key observation is that while an optimal extended labeling can be extended into an optimal labeling of a greater length, the same does not apply to a regular labeling. The problem is that regular labeling corresponds to many extended labelings, which are modified each in a different way during an extension of the regular labeling.

Figure 7.5 of "Supervised Sequence Labelling with Recurrent Neural Networks" dissertation by Alex Graves
Beam Search
To perform a beam search, we keep \( k \) best \textit{regular} (non-extended) labelings. Specifically, for each regular labeling \( y \) we keep both \( \alpha^t_-(y) \) and \( \alpha^t_*(y) \), which are probabilities of all (modulo beam search) extended labelings of length \( t \) which produce the regular labeling \( y \); we therefore keep \( k \) regular labelings with the highest \( \alpha^t_-(y) + \alpha^t_*(y) \).

To compute the best regular labelings for a longer prefix of extended labelings, for each regular labeling in the beam we consider the following cases:

- adding a \textit{blank} symbol, i.e., contributing to \( \alpha^{t+1}_-(y) \) both from \( \alpha^t_-(y) \) and \( \alpha^t_*(y) \);
- adding a non-blank symbol, i.e., contributing to \( \alpha^{t+1}_*(\cdot) \) from \( \alpha^t_-(y) \) and contributing to a possibly different \( \alpha^{t+1}_*(\cdot) \) from \( \alpha^t_*(y) \).

Finally, we merge the resulting candidates according to their regular labeling, and keep only the \( k \) best.
Unsupervised Word Embeddings

The embeddings can be trained for each task separately.

However, a method of precomputing word embeddings have been proposed, based on *distributional hypothesis*:

**Words that are used in the same contexts tend to have similar meanings.**

The distributional hypothesis is usually attributed to Firth (1957):

*You shall know a word by a company it keeps.*
Word2Vec

Mikolov et al. (2013) proposed two very simple architectures for precomputing word embeddings, together with a C multi-threaded implementation word2vec.

*Table 8 of “Efficient Estimation of Word Representations in Vector Space”, https://arxiv.org/abs/1301.3781*
Considering input word $w_i$ and output $w_o$, the Skip-gram model defines

$$p(w_o | w_i) \overset{\text{def}}{=} \frac{e^{V_{w_i}^\top W_{w_o}}}{\sum_w e^{V_{w_i}^\top W_{w}}}.$$ 

After training, the final embeddings are the rows of the $V$ matrix.
Word2Vec – Hierarchical Softmax

Instead of a large softmax, we construct a binary tree over the words, with a sigmoid classifier for each node.

If word \( w \) corresponds to a path \( n_1, n_2, \ldots, n_L \), we define

\[
p_{\text{HS}}(w|w_i) \overset{\text{def}}{=} \prod_{j=1}^{L-1} \sigma([+1 \text{ if } n_{j+1} \text{ is right child else } -1] \cdot V_{w_i}^T W_{n_j}).
\]
Instead of a large softmax, we could train individual sigmoids for all words. We could also only sample several *negative examples*. This gives rise to the following *negative sampling* objective (instead of just summing all the sigmoidal losses):

\[
l_{\text{NEG}}(w_o, w_i) \overset{\text{def}}{=} - \log \sigma(V_{w_i}^\top W_{w_o}) - \sum_{j=1}^{k} \mathbb{E}_{w_j \sim P(w)} \log (1 - \sigma(V_{w_i}^\top W_{w_j})).
\]

The usual value of negative samples \( k \) is 5, but it can be even 2 for extremely large corpora. Each expectation in the loss is estimated using a single sample. For \( P(w) \), both uniform and unigram distribution \( U(w) \) work, but

\[
U(w)^{3/4}
\]

outperforms them significantly (this fact has been reported in several papers by different authors).

**Table 6**: Nearest neighbor words (based on cosine similarity) of word representations from the large word-level and character-level (before and after highway layers) models trained on the PTB. Last three words are OOV words, and therefore they do not have representations in the word-level model.

Table 6 of "Character-Aware Neural Language Models", https://arxiv.org/abs/1508.06615
Another simple idea appeared simultaneously in three nearly simultaneous publications as Charagram, Subword Information or SubGram.

A word embedding is a sum of the word embedding plus embeddings of its character $n$-grams. Such embedding can be pretrained using same algorithms as word2vec.

The implementation can be:

- dictionary based: only some number of frequent character $n$-grams is kept;
- hash-based: character $n$-grams are hashed into $K$ buckets (usually $K \sim 10^6$ is used).
Table 7: Nearest neighbors of rare words using our representations and skipgram. These hand picked examples are for illustration.
