Function Approximation

We will approximate value function $v$ and/or state-value function $q$, selecting it from a family of functions parametrized by a weight vector $w \in \mathbb{R}^d$.

We denote the approximations as

$$\hat{v}(s; w),$$
$$\hat{q}(s, a; w).$$

We utilize the \textit{Mean Squared Value Error} objective, denoted $\overline{VE}$:

$$\overline{VE}(w) \overset{\text{def}}{=} \sum_{s \in S} \mu(s) \left[ v_{\pi}(s) - \hat{v}(s, w) \right]^2,$$

where the state distribution $\mu(s)$ is usually on-policy distribution.
Gradient and Semi-Gradient Methods

The functional approximation (i.e., the weight vector $w$) is usually optimized using gradient methods, for example as

$$w_{t+1} \leftarrow w_t - \frac{1}{2} \alpha \nabla_w \left( v_\pi(S_t) - \hat{v}(S_t; w_t) \right)^2$$

$$\leftarrow w_t + \alpha (v_\pi(S_t) - \hat{v}(S_t; w_t)) \nabla_w \hat{v}(S_t; w_t).$$

As usual, the $v_\pi(S_t)$ is estimated by a suitable sample of a return:

- in Monte Carlo methods, we use episodic return $G_t$,
- in temporal difference methods, we employ bootstrapping and use one-step return

$$R_{t+1} + [-\text{done}] \cdot \gamma \hat{v}(S_{t+1}; w)$$

or an $n$-step return.
Deep Q Network

Off-policy Q-learning algorithm with a convolutional neural network function approximation of action-value function.

Training can be extremely brittle (and can even diverge).

Figure 1 of “Human-level control through deep reinforcement learning” by Volodymyr Mnih et al.
Deep Q Networks

- Preprocessing: 210 × 160 128-color images are converted to grayscale and then resized to 84 × 84.
- Frame skipping technique is used, i.e., only every 4\textsuperscript{th} frame (out of 60 per second) is considered, and the selected action is repeated on the other frames.
- Input to the network are last 4 frames (considering only the frames kept by frame skipping), i.e., an image with 4 channels.
- The network is fairly standard, performing
  - 32 filters of size 8 × 8 with stride 4 and ReLU,
  - 64 filters of size 4 × 4 with stride 2 and ReLU,
  - 64 filters of size 3 × 3 with stride 1 and ReLU,
  - fully connected layer with 512 units and ReLU,
  - output layer with 18 output units (one for each action)
Deep Q Networks

- Network is trained with RMSProp to minimize the following loss:

\[
\mathcal{L} \overset{\text{def}}{=} \mathbb{E}_{(s,a,r,s') \sim \text{data}} \left[ (r + [\neg \text{done}] \cdot \gamma \max_{a'} Q(s', a'; \tilde{\theta}) - Q(s, a; \theta))^2 \right].
\]

- An \( \varepsilon \)-greedy behavior policy is utilized (starts at \( \varepsilon = 1 \) and gradually decreases to 0.1).

Important improvements:

- **experience replay**: the generated episodes are stored in a buffer as \((s, a, r, s')\) quadruples, and for training a transition is sampled uniformly (off-policy training);
- **separate target network \( \tilde{\theta} \)**: to prevent instabilities, a separate target network is used to estimate one-step returns. The weights are not trained, but copied from the trained network after a fixed number of gradient updates;
- **reward clipping**: because rewards have wildly different scale in different games, all positive rewards are replaced by +1 and negative by -1; life loss is used as end of episode.
  - furthermore, \((r + [\neg \text{done}] \cdot \gamma \max_{a'} Q(s', a'; \tilde{\theta}) - Q(s, a; \theta))^2\) is also clipped to \([-1, 1]\) (i.e., a smooth \(L_1\) loss or Huber loss).

There have been many suggested improvements to the DQN architecture. In the end of 2017, the *Rainbow: Combining Improvements in Deep Reinforcement Learning* paper combines 6 of them into a single architecture they call **Rainbow**.

![Figure 1 of "Rainbow: Combining Improvements in Deep Reinforcement Learning" by Matteo Hessel et al.](image-url)
Because behaviour policy in Q-learning is $\epsilon$-greedy variant of the target policy, the same samples (up to $\epsilon$-greedy) determine both the maximizing action and estimate its value.

Figure 6.5 of "Reinforcement Learning: An Introduction, Second Edition".
Double Q-learning

Double Q-learning, for estimating $Q_1 \approx Q_2 \approx q_*$

Algorithm parameters: step size $\alpha \in (0, 1]$, small $\varepsilon > 0$
Initialize $Q_1(s, a)$ and $Q_2(s, a)$, for all $s \in S, a \in A(s)$, such that $Q(\text{terminal}, \cdot) = 0$

Loop for each episode:
  Initialize $S$
  Loop for each step of episode:
    Choose $A$ from $S$ using the policy $\varepsilon$-greedy in $Q_1 + Q_2$
    Take action $A$, observe $R$, $S'$
    With 0.5 probability:
      $$Q_1(S, A) \leftarrow Q_1(S, A) + \alpha \left( R + \gamma Q_2(S', \arg\max_a Q_1(S', a)) - Q_1(S, A) \right)$$
    else:
      $$Q_2(S, A) \leftarrow Q_2(S, A) + \alpha \left( R + \gamma Q_1(S', \arg\max_a Q_2(S', a)) - Q_2(S, A) \right)$$
  $S \leftarrow S'$
  until $S$ is terminal

Double Q-learning

Similarly to double Q-learning, instead of

$$r + \gamma \max_{a'} Q(s', a'; \bar{\theta}) - Q(s, a; \theta),$$

we minimize

$$r + \gamma Q(s', \arg\max_{a'} Q(s', a'; \theta); \bar{\theta}) - Q(s, a; \theta).$$

(Table 2 of "Deep Reinforcement Learning with Double Q-learning" by Hado van Hasselt et al.)
Prioritized Replay

Instead of sampling the transitions uniformly from the replay buffer, we instead prefer those with a large TD error. Therefore, we sample transitions according to their probability

\[ p_t \propto \left| r + \gamma \max_{a'} Q(s', a'; \bar{\theta}) - Q(s, a; \theta) \right|^\omega, \]

where \( \omega \) controls the shape of the distribution (which is uniform for \( \omega = 0 \) and corresponds to TD error for \( \omega = 1 \)).

New transitions are inserted into the replay buffer with maximum probability to support exploration of all encountered transitions.

When combined with DDQN, the probabilities are naturally computed as

\[ p_t \propto \left| r + \gamma Q(s', \arg \max_{a'} Q(s', a'; \theta); \bar{\theta}) - Q(s, a; \theta) \right|^\omega, \]
Prioritized Replay

Because we now sample transitions according to $p_t$ instead of uniformly, on-policy distribution and sampling distribution differ. To compensate, we therefore utilize importance sampling with ratio

$$\rho_t = \left( \frac{1/N}{p_t} \right)^\beta.$$  

The authors utilize in fact “for stability reasons”

$$\rho_t / \max_i \rho_i.$$
Prioritized Replay

Algorithm 1 Double DQN with proportional prioritization

1: **Input**: minibatch $k$, step-size $\eta$, replay period $K$ and size $N$, exponents $\alpha$ and $\beta$, budget $T$.
2: Initialize replay memory $\mathcal{H} = \emptyset$, $\Delta = 0$, $p_1 = 1$
3: Observe $S_0$ and choose $A_0 \sim \pi_\theta(S_0)$
4: for $t = 1$ to $T$ do
5: Observe $S_t, R_t, \gamma_t$
6: Store transition $(S_{t-1}, A_{t-1}, R_t, \gamma_t, S_t)$ in $\mathcal{H}$ with maximal priority $p_t = \max_{i < t} p_i$
7: if $t \equiv 0$ mod $K$ then
8: for $j = 1$ to $k$ do
9: Sample transition $j \sim P(j) = p_j^\alpha / \sum_i p_i^\alpha$
10: Compute importance-sampling weight $w_j = (N \cdot P(j))^{-\beta} / \max_i w_i$
11: Compute TD-error $\delta_j = R_j + \gamma_j Q_{\text{target}}(S_j, \arg \max_a Q(S_j, a)) - Q(S_{j-1}, A_{j-1})$
12: Update transition priority $p_j \leftarrow |\delta_j|$  
13: Accumulate weight-change $\Delta \leftarrow \Delta + w_j \cdot \delta_j \cdot \nabla_\theta Q(S_{j-1}, A_{j-1})$
14: end for
15: Update weights $\theta \leftarrow \theta + \eta \cdot \Delta$, reset $\Delta = 0$
16: From time to time copy weights into target network $\theta_{\text{target}} \leftarrow \theta$
17: end if
18: Choose action $A_t \sim \pi_\theta(S_t)$
19: end for

*Algorithm 1 of "Prioritized Experience Replay" by Tom Schaul et al.*
Dueling Networks

Instead of computing directly $Q(s, a; \theta)$, we compose it from the following quantities:

- value function for a given state $s$,
- advantage function computing an advantage of using action $a$ in state $s$.

\[
Q(s, a) \stackrel{\text{def}}{=} V(f(s; \zeta); \eta) + A(f(s; \zeta), a; \psi) - \sum_{a' \in A} \frac{A(f(s; \zeta), a'; \psi)}{|A|}
\]

Table 1 of "Dueling Network Architectures for Deep Reinforcement Learning" by Ziyu Wang et al.
Multi-step Learning

Instead of Q-learning, we use \( n \)-step variant of Q-learning, which estimates return as

\[
\sum_{i=1}^{n} \gamma^{i-1} R_i + \gamma^n \max_{a'} Q(s', a'; \bar{\theta}).
\]

This changes the off-policy algorithm to on-policy (because the “inner” actions are sampled from the behaviour distribution, but should follow the target distribution); however, it is not discussed in any way by the authors.
Noisy Nets

Noisy Nets are neural networks whose weights and biases are perturbed by a parametric function of a noise. The parameters \( \theta \) of a regular neural network are in Noisy nets represented as

\[
\theta \approx \mu + \sigma \odot \epsilon,
\]

where \( \epsilon \) is zero-mean noise with fixed statistics. We therefore learn the parameters \((\mu, \sigma)\).

A fully connected layer with parameters \((w, b)\),

\[
y = wx + b,
\]

is represented in the following way in Noisy nets:

\[
y = (\mu_w + \sigma_w \odot \epsilon_w)x + (\mu_b + \sigma_b \odot \epsilon_b).
\]
Noisy Nets

The noise $\varepsilon$ can be for example independent Gaussian noise. However, for performance reasons, factorized Gaussian noise is used to generate a matrix of noise. If $\varepsilon_{i,j}$ is noise corresponding to a layer with $i$ inputs and $j$ outputs, we generate independent noise $\varepsilon_i$ for input neurons, independent noise $\varepsilon_j$ for output neurons, and set

$$
\varepsilon_{i,j} = f(\varepsilon_i)f(\varepsilon_j)
$$

for $f(x) = \text{sign}(x)\sqrt{|x|}$.

The authors generate noise samples for every batch, sharing the noise for all batch instances.

Deep Q Networks

When training a DQN, $\varepsilon$-greedy is no longer used and all policies are greedy, and all fully connected layers are parametrized as noisy nets.

Distributional RL

Instead of an expected return $Q(s, a)$, we could estimate the distribution of expected returns $Z(s, a)$.

These distributions satisfy a distributional Bellman equation:

$$Z^\pi(s, a) = R(s, a) + \gamma \mathbb{E}_{s', a'} Z(s', a').$$

The authors of the paper prove similar properties of the distributional Bellman operator compared to the regular Bellman operator, mainly being a contraction under a suitable metric (Wasserstein metric).
Rainbow DQN Extensions

Distributional RL

The distribution of returns is modeled as a discrete distribution parametrized by the number of atoms \( N \in \mathbb{N} \) and by \( V_{\text{MIN}}, V_{\text{MAX}} \in \mathbb{R} \). Support of the distribution are atoms

\[
\{ z_i \overset{\text{def}}{=} V_{\text{MIN}} + i \Delta z : 0 \leq i < N \}
\]

for \( \Delta z \overset{\text{def}}{=} \frac{V_{\text{MAX}} - V_{\text{MIN}}}{N - 1} \).

The atom probabilities are predicted using a softmax distribution as

\[
Z_{\theta}(s, a) = \left\{ z_i \text{ with probability } p_i = \frac{e^{f_i(s,a;\theta)}}{\sum_j e^{f_j(s,a;\theta)}} \right\}.
\]
Distributional RL

After the Bellman update, the support of the distribution $R(s, a) + \gamma Z(s', a')$ is not the same as the original support. We therefore project it to the original support by proportionally mapping each atom of the Bellman update to immediate neighbors in the original support.

$$
\Phi(R(s, a) + \gamma Z(s', a'))_i \overset{\text{def}}{=} \sum_{j=1}^{N} \left[ 1 - \frac{\left[ r + \gamma z_j \right] V_{\text{MAX}} - z_i}{\Delta z} \right] \frac{1}{p_j(s', a')}.
$$

The network is trained to minimize the Kullback-Leibler divergence between the current distribution and the (mapped) distribution of the one-step update

$$
D_{\text{KL}}(\Phi(R + \gamma Z(\theta)(s', \text{arg max}_{a'} \mathbb{E}Z(\theta)(s', a'))) \| Z(\theta)(s, a)).
$$
**Algorithm 1 Categorical Algorithm**

**input** A transition $x_t, a_t, r_t, x_{t+1}, \gamma_t \in [0, 1]$

$Q(x_{t+1}, a) := \sum_i z_i p_i(x_{t+1}, a)$

$a^* \leftarrow \arg \max_a Q(x_{t+1}, a)$

$m_i = 0, \quad i \in 0, \ldots, N - 1$

for $j \in 0, \ldots, N - 1$ do

# Compute the projection of $\hat{T}z_j$ onto the support $\{z_i\}$

$\hat{T}z_j \leftarrow [r_t + \gamma_t z_j] V_{\text{MAX}}$

$b_j \leftarrow (\hat{T}z_j - V_{\text{MIN}}) / \Delta z \quad \# b_j \in [0, N - 1]$

$l \leftarrow [b_j], u \leftarrow [b_j]$

# Distribute probability of $\hat{T}z_j$

$m_l \leftarrow m_l + p_j(x_{t+1}, a^*)(u - b_j)$

$m_u \leftarrow m_u + p_j(x_{t+1}, a^*)(b_j - l)$

end for

**output** $-\sum_i m_i \log p_i(x_t, a_t)$  \# Cross-entropy loss

Figure 3. Categorical DQN: Varying number of atoms in the discrete distribution. Scores are moving averages over 5 million frames.
Rainbow Architecture

Rainbow combines all described DQN extensions. Instead of 1-step updates, $n$-step updates are utilized, and KL divergence of the current and target return distribution is minimized:

$$D_{KL} \left( \Phi \left( \sum_{i=0}^{n-1} \gamma^i R_{t+i+1} + \gamma^n Z_\theta (S_{t+n}, \arg \max_{a'} \mathbb{E} Z_\theta (S_{t+n}, a')) \right) \right) \| Z(S_t, A_t) .$$

The prioritized replay chooses transitions according to the probability

$$p_t \propto D_{KL} \left( \Phi \left( \sum_{i=0}^{n-1} \gamma^i R_{t+i+1} + \gamma^n Z_\theta (S_{t+n}, \arg \max_{a'} \mathbb{E} Z_\theta (S_{t+n}, a')) \right) \right)^w .$$

Network utilizes dueling architecture feeding the shared representation $f(s; \zeta)$ into value computation $V(f(s; \zeta); \eta)$ and advantage computation $A_i(f(s; \zeta), a; \psi)$ for atom $z_i$, and the final probability of atom $z_i$ in state $s$ and action $a$ is computed as

$$p_i(s, a) \overset{\text{def}}{=} \frac{e^{V_i(f(s;\zeta); \eta)+A_i(f(s;\zeta), a; \psi)} - \sum_{a' \in A} A_i(f(s;\zeta), a'; \psi)}{\sum_j e^{V_j(f(s;\zeta); \eta)+A_j(f(s;\zeta), a; \psi)} - \sum_{a' \in A} A_j(f(s;\zeta), a'; \psi)} \cdot |A| .$$
Rainbow Hyperparameters

Finally, we replace all linear layers by their noisy equivalents.
