Discrete Latent Variables

Consider that we would like to have discrete neurons on the hidden layer of a neural network. Note that on the output layer, we relaxed discrete prediction (i.e., an \( \text{arg} \max \)) with a continuous relaxation – \text{softmax}. This way, we can compute the derivatives and also predict the most probable class. (It is possible to derive \text{softmax} as an entropy-regularized \( \text{arg} \max \).)

However, on a hidden layer, we also need to \textit{sample} from the predicted categorical distribution, and then backpropagate the gradients.
Figure 2: Gradient estimation in stochastic computation graphs. (1) $\nabla_\theta f(x)$ can be computed via backpropagation if $x(\theta)$ is deterministic and differentiable. (2) The presence of stochastic node $z$ precludes backpropagation as the sampler function does not have a well-defined gradient. (3) The score function estimator and its variants (NVIL, DARN, MuProp, VIMCO) obtain an unbiased estimate of $\nabla_\theta f(x)$ by backpropagating along a surrogate loss $\hat{f} \log p_\theta(z)$, where $\hat{f} = f(x) - b$ and $b$ is a baseline for variance reduction. (4) The Straight-Through estimator, developed primarily for Bernoulli variables, approximates $\nabla_\theta z \approx 1$. (5) Gumbel-Softmax is a path derivative estimator for a continuous distribution $y$ that approximates $z$. Reparameterization allows gradients to flow from $f(y)$ to $\theta$. $y$ can be annealed to one-hot categorical variables over the course of training.

Figure 2 of "Categorical Reparameterization with Gumbel-Softmax", https://arxiv.org/abs/1611.01144
Stochastic Gradient Estimators

Consider a model with a discrete categorical latent variable $z$ sampled from $p(z; \theta)$, with a loss $L(z; \omega)$. Several gradient estimators have been proposed:

- A REINFORCE-like gradient estimation.
  Using the identity $\nabla_\theta p(z; \theta) = p(z; \theta) \nabla_\theta \log p(z; \theta)$, we obtain that

  $$\nabla_\theta \mathbb{E}_z [L(z; \omega)] = \mathbb{E}_z [L(z; \omega) \nabla_\theta \log p(z; \theta)].$$

  Analogously as before, we can also include the baseline for variance reduction, resulting in

  $$\nabla_\theta \mathbb{E}_z [L(z; \omega)] = \mathbb{E}_z [(L(z; \omega) - b) \nabla_\theta \log p(z; \theta)].$$

- A **straight-through (ST)** estimator.
  The straight-through estimator has been proposed by Y. Bengio in 2013. It is a biased estimator, which assumes that $\nabla_\theta z \approx \nabla_\theta p(z; \theta)$, which implies $\nabla p(z; \theta) z \approx 1$. Even if the bias can be considerable, it seems to work quite well in practice.
The **Gumbel-softmax** distribution was proposed independently in two papers in Nov 2016 (under the name of **Concrete** distribution in the other paper).

It is a continuous distribution over the simplex (over categorical distributions) that can approximate sampling from a categorical distribution.

Let \( z \) be a categorical variable with class probabilities \( p = (p_1, p_2, \ldots, p_K) \).

The Gumbel-Max trick (based on a 1954 theorem from E. J. Gumbel) states that we can draw samples \( z \sim p \) using

\[
z = \text{one-hot} \left( \arg \max_i (g_i + \log p_i) \right),
\]

where \( g_i \) are independent samples drawn from the Gumbel(0, 1) distribution.

To sample \( g \) from the distribution Gumbel(0, 1), we can sample \( u \sim U(0, 1) \) and then compute \( g = -\log(-\log u) \).
First recall that exponential distribution $\text{Exp}(\lambda)$ has

$$\text{PDF}(x; \lambda) = \lambda e^{-\lambda x}, \quad \text{CDF}(x; \lambda) = 1 - e^{-\lambda x}.$$ 

The standard Gumbel$(0, 1)$ distribution has

$$\text{PDF}(x) = e^{-x - e^{-x}}, \quad \text{CDF}(x) = e^{-e^{-x}}.$$ 

The Gumbel distribution can be used to model the distribution of maximum of a number of samples from the exponential distribution: if $\tilde{x}$ is a maximum of $N$ samples from the $\text{Exp}(1)$ distribution, we get that

$$P(\tilde{x} - \log N \leq x) = P(\tilde{x} \leq x + \log N) = \text{CDF}_{\text{Exp}(1)}(x + \log N)^N = \left(1 - \frac{e^{-x}}{N}\right)^N,$$

which converges to $e^{-e^{-x}} = \text{CDF}_{\text{Gumbel}(0,1)}(x)$ for $N \to \infty$. 
To prove the Gumbel-Max trick, we first reformulate it slightly. Let $l_i$ be logits of a categorical distribution (so that the class probabilities $\pi_i \propto e^{l_i}$), and let $g_i \sim \text{Gumbel}(0, 1)$. Then

$$\pi_k = P(k = \arg \max_i (g_i + l_i)).$$

We first observe that the theorem is invariant to a scalar shift of logits, so we can without loss of generality assume that $\sum_i e^{l_i} = 1$ and $\pi_i = e^{l_i}$.

For convenience, denote $u_i \overset{\text{def}}{=} g_i + l_i$.

We will use both the PDF and CDF of a $\text{Gumbel}(0, 1)$ distribution:

$$\text{PDF}(g_i) = e^{-g_i - e^{-g_i}},$$
$$\text{CDF}(g_i) = e^{-e^{-g_i}}.$$
Gumbel-Max Trick Proof

To finish the proof, we compute

\[ P(k = \text{arg max}_i (g_i + l_i)) = P(u_k \geq u_i, \forall i \neq k) \]

\[ = \int P(u_k) \prod_{i \neq k} P(u_k \geq u_i | u_k) \, du_k \]

\[ = \int P(g_k | g_k = u_k - l_k) \prod_{i \neq k} P(g_i \leq u_k - l_i | u_k) \, du_k \]

\[ = \int e^{l_k - u_k - e^{-l_k - u_k}} \prod_{i \neq k} e^{-e^{-l_i - u_k}} \, du_k \]

\[ = \int \pi_k e^{-u_k - \pi_k e^{-u_k}} \prod_{i \neq k} e^{-\pi_i e^{-u_k}} \, du_k \]

\[ = \pi_k \int e^{-u_k - e^{-u_k}} \sum_{i} \pi_i \, du_k \]

\[ = \pi_k \int e^{-g_k - e^{-g_k}} \, dg_k = \pi_k \cdot 1 = \pi_k. \]
Gumbel-Softmax

To obtain a continuous distribution, we relax the arg max into a softmax with temperature \( T \) as

\[
z_i = \frac{e^{(g_i + \log p_i)/T}}{\sum_j e^{(g_j + \log p_j)/T}}.
\]

As the temperature \( T \) goes to zero, the generated samples become one-hot, and therefore the Gumbel-softmax distribution converges to the categorical distribution \( p(z) \).

Figure 1 of "Categorical Reparameterization with Gumbel-Softmax", https://arxiv.org/abs/1611.01144
The Gumbel-softmax distribution can be used to reparametrize the sampling of the discrete variable using a fully differentiable estimator. However, the resulting sample is not discrete, it only converges to a discrete sample as the temperature $T$ goes to zero.

If it is a problem, we can combine the Gumbel-softmax with a straight-through estimator, obtaining ST Gumbel-softmax, where we:

- discretize $y$ as $z = \arg \max y$,
- assume $\nabla_\theta z \approx \nabla_\theta y$, or in other words, $\frac{\partial z}{\partial y} \approx 1$.

Figure 2 of "Categorical Reparameterization with Gumbel-Softmax", https://arxiv.org/abs/1611.01144
Gumbel-Softmax Estimator Results

Table 1: The Gumbel-Softmax estimator outperforms other estimators on Bernoulli and Categorical latent variables. For the structured output prediction (SBN) task, numbers correspond to negative log-likelihoods (nats) of input images (lower is better). For the VAE task, numbers correspond to negative variational lower bounds (nats) on the log-likelihood (lower is better).

Applications of Discrete Latent Variables

The discrete latent variables can be used among others to:

- allow the SAC algorithm to be used on **discrete** actions, using either Gumbel-softmax relaxation (if the critic takes the actions as binary indicators, it is possible to pass not just one-hot encoding, but the result of Gumbel-softmax directly), or a straight-through estimator;

- model images using discrete latent variables
  - VQ-VAE, VQ-VAE-2 use “codebook loss” with a straight-through estimator

![Diagram of VQ-VAE](https://example.com/vq-vae-diagram)

*Figure 1 of “Neural Discrete Representation Learning”, https://arxiv.org/abs/1711.00937*
Applications of Discrete Latent Variables

- VQ-GAN combines the VQ-VAE and Transformers, where the latter is used to generate a sequence of the discrete latents.

Figure 2 of "Taming Transformers for High-Resolution Image Synthesis”, https://arxiv.org/abs/2012.09841
In DALL-E, Transformer is used to model a sequence of words followed by a sequence of the discrete image latent variables.

The Gumbel-softmax relaxation is used to train the discrete latent states, with temperature annealed with a cosine decay from 1 to $1/16$ over the first 150k (out of 3M) updates.

(a) a tapir made of accordion. (b) an illustration of a baby hedgehog in a christmas sweater walking a dog (c) a neon sign that reads “backprop”. (d) the exact same cat on the top as a sketch on the bottom

Figure 2 of “Zero-Shot Text-to-Image Generation”, https://arxiv.org/abs/2102.12092
The PlaNet model was followed by Dreamer (Dec 2019) and DreamerV2 (Oct 2020), which train an agent using reinforcement learning using the model alone. After 200M environment steps, it surpasses Rainbow on a collection of 55 Atari games (the authors do not mention why they do not use all 57 games) when training on a single GPU for 10 days per game.

During training, a policy is learned from 486B compact states “dreamed” by the model, which is 10,000 times more than the 50M observations from the real environment (with action repeat 4).

Interestingly, the latent states are represented as a vector of several categorical variables – 32 variables with 32 classes each are utilized in the paper.
The model in DreamerV2 is learned using the RSSM, collecting agent experiences of observations, actions, rewards, and discount factors (0.995 within episode and 0 at an episode end). Training is performed on batches of 50 sequences of length at most 50 each.

**Algorithm 1: Straight-Through Gradients with Automatic Differentiation**

```python
sample = one_hot(draw(logits))  # sample has no gradient
probs = softmax(logits)         # want gradient of this
sample = sample + probs - stop_grad(probs)  # has gradient of probs
```

DreamerV2 – Model Learning

The following loss function is used:

\[
\mathcal{L}(\phi) = \mathbb{E}_{q_\phi(s_{1:T}|a_{1:T},x_{1:T})} \left[ \sum_{t=1}^{T} \left( -\log p_\phi(x_t|h_t, s_t) - \log p_\phi(r_t|h_t, s_t) - \log p_\phi(\gamma_t|h_t, s_t) \right) + \beta D_{KL} \left[ q_\phi(s_t|h_t, x_t) \parallel p_\phi(s_t|h_t) \right] \right].
\]

In the KL term, we train both the prior and the encoder. However, regularizing the encoder towards the prior makes training harder (especially at the beginning), so the authors propose **KL balancing**, minimizing the KL term faster for the prior ($\alpha = 0.8$) than for the posterior.

**Algorithm 2: KL Balancing with Automatic Differentiation**

```
kl_loss = alpha * compute_kl(stop_grad(approx_posterior), prior) + (1 - alpha) * compute_kl(approx_posterior, stop_grad(prior))
```

The policy is trained solely from the model, starting from the encountered posterior states and then considering $H = 15$ actions simulated in the compact latent state.

We train an actor predicting $\pi_{\psi}(a_t | s_t)$ and a critic predicting

$$v_\xi(s_t) = \mathbb{E}_{p_\varphi, \pi_\psi} \left[ \sum_{t \geq t} (\prod_{r' = t+1}^{r'} \gamma r') r_t \right].$$

The critic is trained by estimating the truncated $\lambda$-return as

$$V_t^\lambda = r_t + \gamma_t \begin{cases} (1 - \lambda)v_\xi(\hat{z}_{t+1}) + \lambda V_{t+1}^\lambda & \text{if } t < H, \\ v_\xi(\hat{z}_H) & \text{if } t = H. \end{cases}$$

and then minimizing the MSE.
DreamerV2 – Policy Learning

The actor is trained using two approaches:

- the REINFORCE-like loss (with a baseline), which is unbiased, but has a high variance (even with the baseline);
- the reparametrization of discrete actions using a straight-through gradient estimation, which is biased, but has lower variance.

\[
\mathcal{L}(\psi) = \mathbb{E}_{p_\psi, \pi_\psi} \left[ \sum_{t=1}^{H-1} \left( -\rho \log \pi_\psi(a_t|s_t) \text{ stop_gradient}(V_t^\lambda - v_\xi(s_t)) \right) \right]
\]

\[
\begin{align*}
&\text{reinforce} \quad -\rho \log \pi_\psi(a_t|s_t) \text{ stop_gradient}(V_t^\lambda - v_\xi(s_t)) \\
&\text{dynamics backprop} \quad -(1 - \rho)V_t^\lambda \\
&\text{entropy regularizer} \quad -\eta H(a_t|s_t)
\end{align*}
\]

For Atari domains, authors use $\rho = 1$ and $\eta = 10^{-3}$, while for continuous actions, $\rho = 1$ works better (presumably because of the bias in case of discrete actions) and $\eta = 10^{-4}$ is used.
The authors evaluate on 55 Atari games. They argue that the commonly used metrics have various flaws:

- **gamer-normalized median** ignores scores on half of the games,
- **gamer-normalized mean** is dominated by several games where the agent achieves super-human performance by several orders.

They therefore propose two additional ones:

- **record-normalized mean** normalizes with respect to any registered human world record for each game; however, in some games the agents still achieve super-human-record performance;
- **clipped record-normalized mean** additionally clips each score to 1; this measure is used as the primary metric in the paper.

Categorical latent variables outperform Gaussian latent variables on 42 games, tie on 5 games and decrease performance on 8 games (where a tie is defined as being within 5%).

The authors provide several hypotheses why could the categorical latent variables be better:

- Categorical prior can perfectly match aggregated posterior, because mixture of categoricals is categorical, which is not true for Gaussians.

- Sparsity achieved by the 32 categorical variables with 32 classes each could be beneficial for generalization.

- Contrary to intuition, optimizing categorical variables might be easier than optimizing Gaussians, because the straight-through estimator ignores a term which would otherwise scale the gradient, which could reduce exploding/vanishing gradient problem.

- Categorical variables could be a better match for modeling discrete aspect of the Atari games (defeating an enemy, collecting reward, entering a room, ...).

In a partially-observable environment, keeping all information in the RNN state is substantially limiting. Therefore, *memory-augmented* networks can be used to store suitable information in external memory (in the lines of NTM, DNC, or MANN models).

We now describe an approach used by Merlin architecture (*Unsupervised Predictive Memory in a Goal-Directed Agent* DeepMind Mar 2018 paper).

**a. RL-LSTM**

**b. RL-MEM**
Let $M$ be a memory matrix of size $N_{mem} \times 2|e|$.

Assume we have already encoded observations as $e_t$ and previous action $a_{t-1}$. We concatenate them with $K$ previously read vectors and process them by a deep LSTM (two layers are used in the paper) to compute $h_t$.

Then, we apply a linear layer to $h_t$, computing $K$ key vectors $k_1, \ldots, k_K$ of length $2|e|$ and $K$ positive scalars $\beta_1, \ldots, \beta_K$.

**Reading:** For each $i$, we compute cosine similarity of $k_i$ and all memory rows $M_j$, multiply the similarities by $\beta_i$ and pass them through a $\text{softmax}$ to obtain weights $\omega_i$. The read vector is then computed as $M\omega_i$.

**Writing:** We find one-hot write index $v_{wr}$ to be the least used memory row (we keep usage indicators and add read weights to them). We then compute $v_{ret} \leftarrow \gamma v_{ret} + (1 - \gamma) v_{wr}$, and retroactively update the memory matrix using $M \leftarrow M + v_{wr}[e_t, 0] + v_{ret}[0, e_t]$. 

*Figure 1b of "Unsupervised Predictive Memory in a Goal-Directed Agent", https://arxiv.org/abs/1803.10760*
However, updating the encoder and memory content purely using RL is inefficient. Therefore, MERLIN includes a memory-based predictor (MBP) in addition to policy. The goal of MBP is to compress observations into low-dimensional state representations $z$ and storing them in memory.

We want the state variables not only to faithfully represent the data, but also emphasise rewarding elements of the environment above irrelevant ones. To accomplish this, the authors follow the hippocampal representation theory of Gluck and Myers, who proposed that hippocampal representations pass through a compressive bottleneck and then reconstruct input stimuli together with task reward.

In MERLIN, a (Gaussian diagonal) *prior* distribution over $z_t$ predicts next state variable conditioned on history of state variables and actions $p(z^\text{prior}_t | z_{t-1}, a_{t-1}, \ldots, z_1, a_1)$, and *posterior* corrects the prior using the new observation $o_t$, forming a better estimate $q(z_t | o_t, z^{\text{prior}}_t, z_{t-1}, a_{t-1}, \ldots, z_1, a_1) + z^{\text{prior}}_t$. 
To achieve the mentioned goals, we add two terms to the loss.

- We try reconstructing input stimuli, action, reward and return using a sample from the state variable posterior, and add the difference of the reconstruction and ground truth to the loss.
- We also add KL divergence of the prior and the posterior to the loss, to ensure consistency between the prior and the posterior.

For the Win agent for Capture The Flag

(a) FTW Agent Architecture

(b) Progression During Training

Figure 2 of "Human-level performance in first-person multiplayer games with population-based deep reinforcement learning" by Max Jaderber et al.
For the Win agent for Capture The Flag

- Extension of the MERLIN architecture.
- Hierarchical RNN with two timescales.
- Population based training controlling KL divergence penalty weights, internal dense rewards, slow ticking RNN speed, and gradient flow factor from fast to slow RNN.

In every game, teams of similarly skilled agents were selected, and the authors state it is crucial to employ several agents instead of just one (30 simultaneously trained agents are used).
