Linear Regression
Organization

Course Website: https://ufal.mff.cuni.cz/courses/npfl129
- Slides, recordings, assignments, exam questions

Course Repository: https://github.com/ufal/npfl129
- Templates for the assignments, slide sources.

Piazza
- Piazza will be used as a communication platform.
  - You can post questions or notes,
    - privately to the instructors,
    - publicly to everyone (signed or anonymously).
      - Other students can answer these too, which allows you to get faster response.
      - However, do not include even parts of your source code in public questions.

- Please use Piazza for all communication with the instructors.
- You will get the invite link after the first lecture.
https://recodex.mff.cuni.cz

- The assignments will be evaluated automatically in ReCodEx.
- If you have a MFF SIS account, you should be able to create an account using your CAS credentials and should automatically see the right group.
- Otherwise, there will be instructions on Piazza how to get ReCodEx account (generally you will need to send me a message with several pieces of information and I will send it to ReCodEx administrators in batches).
Practicals

- There will be about 2-3 assignments a week, each with a 2-week deadline.
  - There is also another week-long second deadline, but for less points.
- After solving the assignment, you get non-bonus points, and sometimes also bonus points.
- To pass the practicals, you need to get 80 non-bonus points. There will be assignments for at least 120 non-bonus points.
- If you get more than 80 points (be it bonus or non-bonus), they will be transferred to the exam (but at most 40 points are transferred).

Lecture

You need to pass a written exam.

- All questions are publicly listed on the course website.
- There are questions for 100 points in every exam, plus at most 40 surplus points from the practicals and plus at most 10 surplus points for community work (improving slides, ...).
- You need 60/75/90 points to pass with grade 3/2/1.
A possible definition of learning from Mitchell (1997):

A computer program is said to learn from experience E with respect to some class of
tasks T and performance measure P, if its performance at tasks in T, as measured by P,
improves with experience E.

- **Task T**
  - *classification*: assigning one of $k$ categories to a given input
  - *regression*: producing a number $x \in \mathbb{R}$ for a given input
  - *structured prediction, denoising, density estimation, ...*

- **Measure P**
  - *accuracy, error rate, F-score, ...*

- **Experience E**
  - *supervised*: usually a dataset with desired outcomes (*labels or targets*)
  - *unsupervised*: usually data without any annotation (raw text, raw images, ...)
  - *reinforcement learning, semi-supervised learning, ...*
Supervised Machine Learning

Basic Machine Learning Settings

Assume we have an input of $\mathbf{x} \in \mathbb{R}^D$. The two basic ML tasks are:

1. **regression**: The goal of regression is to predict a real-valued target variable $t \in \mathbb{R}$ for the given input.

2. **classification**: Assuming we have a fixed set of $K$ labels, the goal of a classification is to choose a corresponding label/class for a given input.
   - We can predict the class only.
   - We can predict the whole distribution of all classes probabilities.

We usually have a **training set**, which is assumed to consist of examples of $(\mathbf{x}, t)$ generated independently from a **data-generating distribution**.

The goal of **optimization** is to match the training set as well as possible.

However, the goal of **machine learning** is to perform well on *previously unseen* data, to achieve the lowest **generalization error** or **test error**. We typically estimate it using a **test set** of examples independent of the training set, but generated by the same data-generating distribution.
Notation

- $a, \ a, \ A, \ A$: scalar (integer or real), vector, matrix, tensor
  - all vectors are always **column** vectors
  - transposition changes a column vector into a row vector, so $a^T$ is a row vector
  - we denote the **dot (scalar) product** of the vectors $a$ and $b$ using $a^Tb$
    - we understand it as matrix multiplication
  - the $\|a\|_2$ or just $\|a\|$ is the Euclidean (or $L^2$) norm
    - $\|a\|_2 = \sqrt{\sum_i a_i^2}$

- $a, \ a, \ A$: scalar, vector, matrix random variable

- $\frac{df}{dx}$: derivative of $f$ with respect to $x$

- $\frac{\partial f}{\partial x}$: partial derivative of $f$ with respect to $x$

- $\nabla_x f(x)$: gradient of $f$ with respect to $x$, i.e., $(\frac{\partial f(x)}{\partial x_1}, \frac{\partial f(x)}{\partial x_2}, \ldots, \frac{\partial f(x)}{\partial x_n})$
Assume we have the following data, generated from an underlying curve by adding a small amount of noise.

Figure 1.2 of Pattern Recognition and Machine Learning.
Input Data

Usually, our machine learning algorithms will be trained using the train set $X \in \mathbb{R}^{N \times D}$, which is a collection of $N$ instances, each represented by $D$ real numbers.

In supervised learning, we also have a target $t$ for every instance,

- a real number for regression, $t \in \mathbb{R}^{N}$;
- a class for classification, $t \in \{0, 1, \ldots, K - 1\}^{N}$.

The input to machine learning algorithms is frequently preprocessed, i.e., the algorithms do not always work directly on the input $X$, but on some modification of it. These preprocessed input values are called features.

In literature, the collection of the processed inputs is called a design matrix $\Phi \in \mathbb{R}^{N \times M}$. However, we will denote the inputs to algorithms always as $X$, be it the original training data or processed features.
Given an input value \( \mathbf{x} \in \mathbb{R}^D \), one of the simplest models to predict a target real value is linear regression:

\[
y(\mathbf{x}; \mathbf{w}, b) = x_1 w_1 + x_2 w_2 + \ldots + x_D w_D + b = \sum_{i=1}^{D} x_i w_i + b = \mathbf{x}^T \mathbf{w} + b.
\]

The \( \mathbf{w} \) are usually called *weights* and \( b \) is called *bias*.

Sometimes it is convenient not to deal with the bias separately. Instead, we might enlarge the input vector \( \mathbf{x} \) by padding a value 1, and consider only \( \mathbf{x}^T \mathbf{w} \), where the role of a bias is accomplished by the last weight. Therefore, when we say “weights”, we usually mean both weights and biases.
Separate Bias vs. Padding $X$ with Ones

Using an explicit bias term in the form of $y(x) = x^T w + b$.

$$
\begin{bmatrix}
x_{11} & x_{12} \\
x_{21} & x_{22} \\
\vdots \\
x_{n1} & x_{n2}
\end{bmatrix} \cdot \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} + b = 
\begin{bmatrix}
w_1 x_{11} + w_2 x_{12} + b \\
w_1 x_{21} + w_2 x_{22} + b \\
\vdots \\
w_1 x_{n1} + w_2 x_{n2} + b
\end{bmatrix}
$$

With extra 1 padding in $X$ and an additional $b$ weight representing the bias.

$$
\begin{bmatrix}
x_{11} & x_{12} & 1 \\
x_{21} & x_{22} & 1 \\
\vdots \\
x_{n1} & x_{n2} & 1
\end{bmatrix} \cdot \begin{bmatrix} w_1 \\ w_2 \\ b \end{bmatrix} = 
\begin{bmatrix}
w_1 x_{11} + w_2 x_{12} + b \\
w_1 x_{21} + w_2 x_{22} + b \\
\vdots \\
w_1 x_{n1} + w_2 x_{n2} + b
\end{bmatrix}
$$
Linear Regression

Assume we have a dataset of $N$ input values $\mathbf{x}_1, \ldots, \mathbf{x}_N$ and targets $t_1, \ldots, t_N$.

To find the values of weights, we usually minimize an error function between the real target values and their predictions.

A popular and simple error function is mean squared error:

$$\text{MSE}(\mathbf{w}) = \frac{1}{N} \sum_{i=1}^{N} (y(\mathbf{x}_i; \mathbf{w}) - t_i)^2.$$ 

Often, sum of squares

$$\frac{1}{2} \sum_{i=1}^{N} (y(\mathbf{x}_i; \mathbf{w}) - t_i)^2$$

is used instead, because minimizing it is equal to minimizing MSE, but the math comes out nicer.
There are several ways how to minimize the error function, but in the case of linear regression and sum of squares error, there exists an explicit solution.

Our goal is to minimize the following quantity:

$$\frac{1}{2} \sum_{i=1}^{N} (x_i^T w - t_i)^2.$$ 

If we denote $X \in \mathbb{R}^{N \times D}$ the matrix of input values with $x_i$ on a row $i$ and $t \in \mathbb{R}^N$ the vector of target values, we can rewrite the minimized quantity as

$$\frac{1}{2} \|Xw - t\|^2,$$

because

$$\|Xw - t\|^2 = \sum_i ((Xw - t)_i)^2 = \sum_i ((Xw)_i - t_i)^2 = \sum_i (x_i^T w - t_i)^2.$$
Minimization – Unconstrained, Single Real Variable

Assume we have a function and we want to find its minimum.

We usually use the Fermat’s theorem (interior extremum theorem):
Let \( f : \mathbb{R} \rightarrow \mathbb{R} \) be a function. If it has minimum (or maximum) in \( x \) and if it has derivative in \( x \), then

\[
\frac{\partial f}{\partial x} = 0.
\]
The previous theorem can be generalized to the multivariate case:

Let \( f : \mathbb{R}^D \rightarrow \mathbb{R} \) be a function. If it has minimum (or maximum) in \( \mathbf{x} = (x_1, x_2, \ldots, x_D) \) and if it has derivative in \( \mathbf{x} \), then for all \( i \), \( \frac{\partial f}{\partial x_i} = 0 \). In other words, \( \nabla_x f(\mathbf{x}) = 0 \).
In order to find a minimum of $\frac{1}{2} \sum_{i}^{N} (x_i^T w - t_i)^2$, we can inspect values where the derivative of the error function is zero, with respect to all weights $w_j$.

$$\frac{\partial}{\partial w_j} \frac{1}{2} \sum_{i}^{N} (x_i^T w - t_i)^2 = \frac{1}{2} \sum_{i}^{N} (2(x_i^T w - t_i)x_{ij}) = \sum_{i}^{N} x_{ij}(x_i^T w - t_i)$$

Therefore, we want for all $j$ that $\sum_{i}^{N} x_{ij}(x_i^T w - t_i) = 0$.

We can rewrite the explicit sum into $X_{*,j}^T (Xw - t) = 0$, then write the equations for all $j$ together using matrix notation as $X^T (Xw - t) = 0$, and finally, rewrite to

$$X^T Xw = X^T t.$$ 

The matrix $X^T X$ is of size $D \times D$. If it is regular, we can compute its inverse and therefore

$$w = (X^T X)^{-1} X^T t.$$
**Linear Regression**

**Input:** Dataset \((X \in \mathbb{R}^{N \times D}, t \in \mathbb{R}^N)\).

**Output:** Weights \(w \in \mathbb{R}^D\) minimizing MSE of linear regression.

- \(w \leftarrow (X^T X)^{-1} X^T t\).

The algorithm has complexity \(O(ND^2)\), assuming \(N \geq D\).

When the matrix \(X^T X\) is singular, we can solve \(X^T X w = X^T t\) using SVD, which will be demonstrated on the next lecture.
Linear Regression Example

Assume we want to predict a $t \in \mathbb{R}$ for a given $x \in \mathbb{R}$. If we train the linear regression with “raw” input vectors $\mathbf{x} = (x)$, only straight lines could be modeled.

However, if we consider input vectors $\mathbf{x} = (x^0, x^1, \ldots, x^M)$ for a given $M \geq 0$, the linear regression is able to model polynomials of degree $M$, because the prediction is then computed as

$$w_0 x^0 + w_1 x^1 + \ldots + w_M x^M.$$  

Therefore, the weights are the coefficients of a polynomial of degree $M$. 
To plot the error, the *root mean squared error* $\text{RMSE} = \sqrt{\text{MSE}}$ is frequently used.

The displayed error nicely illustrates two main challenges in machine learning:

- *underfitting*
- *overfitting*
