Sequence-to-Sequence Architecture
Sequence-to-Sequence is a name for an architecture allowing to produce an arbitrary output sequence $y_1, \ldots, y_M$ from an input sequence $x_1, \ldots, x_N$.

Unlike span labeling/CTC, no assumptions are necessary and we condition each output sequence element on all input sequence elements and all already generated output sequence elements:

$$P(y \mid X) = \prod_{i=1}^{M} P(y_i \mid x_1, \ldots, x_N, y_1, \ldots, y_{i-1}).$$
Sequence-to-Sequence Architecture

Sequence-to-Sequence Architecture

Training
The so-called teacher forcing is used during training – the gold outputs are used as inputs during training.

Inference
During inference, the network processes its own predictions – such an approach is called autoregressive decoding.

Usually, the generated logits are processed by an arg max, the chosen word embedded and used as next input.
Tying Word Embeddings

In the decoder, we both:

- embed the previous prediction, using a matrix of size $\mathbb{R}^{V \times D}$, where $V$ is the vocabulary size and $D$ is the embedding size;
- classify the hidden state into current prediction, using a matrix of size $\mathbb{R}^{D \times V}$.

Both these matrices have similar meaning – they represent words in the embedding space (the first explicitly represents words by the embeddings, the second produces logits by computing weighted cosine similarity of the inputs and columns of the weight matrix).

Therefore, it makes sense to tie these matrices, i.e., to represent one of them as a transposition of the other.

- However, while the embedding matrix should usually have constant variance per dimension, the output layer should keep the variance of the RNN output; therefore, the output layer matrix is usually the embedding matrix divided by $\sqrt{D}$.
Attention

Diagram of an attention mechanism in a seq2seq model.
Bahdanau Attention

As another input during decoding, we add context vector $c_i$:

$$s_i = f(s_{i-1}, y_{i-1}, c_i).$$

We compute the context vector as a weighted combination of source sentence encoded outputs:

$$c_i = \sum_j \alpha_{ij} h_j$$

The weights $\alpha_{ij}$ are softmax of $e_{ij}$ over $j$, 

$$\alpha_i = \text{softmax}(e_i),$$

with $e_{ij}$ being 

$$e_{ij} = \mathbf{v}^\top \tanh(\mathbf{V}h_j + \mathbf{W}s_{i-1} + b).$$
Bahdanau Attention Implementation

\[
\begin{align*}
    s_{i-1} & \rightarrow \text{tanh} \\
h_1 & \rightarrow \text{softmax} \\
    s_{i-1} & \rightarrow \text{tanh} \\
h_2 & \\
    \vdots & \\
    s_{i-1} & \rightarrow \text{tanh} \\
h_N & \rightarrow \text{softmax} \\
\end{align*}
\]
Trained Attention Visualization

Figure 3 of "Neural Machine Translation by Jointly Learning to Align and Translate", https://arxiv.org/abs/1409.0473
In the described *Bahdanau* (or *additive*) attention, we performed

\[ e_{ij} = \mathbf{v}^\top \tanh(\mathbf{V} \mathbf{h}_j + \mathbf{W} \mathbf{s}_{i-1} + \mathbf{b}) . \]

There are however other methods how \( \mathbf{V} \mathbf{h}_j \) and \( \mathbf{W} \mathbf{s}_{i-1} \) can be combined, most notably the *Luong* (or *dot-product*) attention, which uses just a dot product:

\[ e_{ij} = (\mathbf{V} \mathbf{h}_j)^T (\mathbf{W} \mathbf{s}_{i-1}) . \]

The latter is easier to implement, but may sometimes be more difficult to train (scaling helps a bit, wait for the Transformer self-attention description); both approaches are used in quite a few papers.
Subword Units

Translate **subword units** instead of words. The subword units can be generated in several ways, the most commonly used are:

- **BPE**: Using the *byte pair encoding* algorithm. Start with individual characters plus a special end-of-word symbol •. Then, merge the most occurring symbol pair $A, B$ by a new symbol $AB$, with the symbol pair never crossing word boundary (so that the end-of-word symbol cannot be inside a subword).

  Considering text with words *low, lowest, newer, wider*, a possible sequence of merges:

  $$
  r \cdot \rightarrow r• \\
  l\ o \rightarrow lo \\
  lo\ w \rightarrow low \\
  e \ r• \rightarrow er•
  $$

  The BPE algorithm is executed on the training data, and it generates the resulting dictionary, merging rules, and training data encoded using this dictionary.
Subword Units

- **Wordpieces**: Given a text divided into subwords, we can compute unigram probability of every subword, and then get the likelihood of the text under a unigram language model by multiplying the probabilities of the subwords in the text.

When we have only a text and a subword dictionary, we divide the text in a greedy fashion, iteratively choosing the longest existing subword.

When constructing the subwords, we again start with individual characters (compared to BPE, we have a *start-of-word* character instead of an *end-of-word* character), and then repeatedly join such a pair of subwords that increases the unigram language model likelihood the most.

- In the original implementation, the input data were once in a while “reparsed” (retokenized) in a greedy fashion with the up-to-date dictionary. However, the recent implementations do not seem to do it — but they retokenize the training data with the final dictionary, contrary to the BPE approach.

For both approaches, usually quite little subword units are used (32k-64k), often generated on the union of the two vocabularies of the source and target languages (the so-called joint BPE or shared wordpieces).
Both the BPE and the WordPieces give very similar results; the biggest difference is that during the inference:

- for BPE, the sequence of merges must be performed in the same order as during the construction of the BPE (because we use the output of BPE as training data),
- for Wordpieces, it is enough to find longest matches from the subword dictionary (because we reprocessed the training data with the final dictionary);
- note that the above difference is mostly artificial – if we reparsed the training data in the BPE approach, we could also perform “greedy tokenization”.

Of course, the two algorithms also differ in the way how they choose the pair of subwords to merge.

Both algorithms are implemented in quite a few libraries, most notably the sentencepiece library and the Hugging Face tokenizers package.

Multilingual and Unsupervised Translation

Many attempts at multilingual translation.

- Individual encoders and decoders, shared attention.
- Shared encoders and decoders.

Surprisingly, even unsupervised translation is attempted lately. By unsupervised we understand settings where we have access to large monolingual corpora, but no parallel data.

In 2019, the best unsupervised systems were on par with the best 2014 supervised systems.

*Table 3 of “An Effective Approach to Unsupervised Machine Translation”, https://arxiv.org/abs/1902.01313*
For some sequence processing tasks, *sequential* processing (as performed by recurrent neural networks) of its elements might be too restrictive.

Instead, we may want to be able to combine sequence elements independently on their distance. Such processing is allowed in the **Transformer** architecture, originally proposed for neural machine translation in 2017 in *Attention is All You Need* paper.

Transformer – Self-Attention

Assume that we have a sequence of \( n \) words represented using a matrix \( X \in \mathbb{R}^{n \times d} \).

The attention module for queries \( Q \in \mathbb{R}^{n \times d_k} \), keys \( K \in \mathbb{R}^{n \times d_k} \) and values \( V \in \mathbb{R}^{n \times d_v} \) is defined as:

\[
\text{Attention}(Q, K, V) = \text{softmax} \left( \frac{QK^\top}{\sqrt{d_k}} \right) V.
\]

The queries, keys and values are computed from the input word representations \( X \) using a linear transformation as

\[
Q = X W^Q \\
K = X W^K \\
V = X W^V
\]

for trainable weight matrices \( W^Q, W^K \in \mathbb{R}^{d \times d_k} \) and \( W^V \in \mathbb{R}^{d \times d_v} \).

\end{align*}
\]

Transformer – Multihead Attention

Multihead attention is used in practice. Instead of using one huge attention, we split queries, keys and values to several groups (similar to how ResNeXt works), compute the attention in each of the groups separately, concatenate the results and multiply them by a matrix $W^O$.

...
Figure 1 of "Attention Is All You Need", https://arxiv.org/abs/1706.03762
Masked Self-Attention

During decoding, the self-attention must attend only to earlier positions in the output sequence. This is achieved by masking future positions, i.e., zeroing their weights out, which is usually implemented by setting them to $-\infty$ before the softmax calculation.

Encoder-Decoder Attention

In the encoder-decoder attentions, the queries comes from the decoder, while the keys and the values originate from the encoder.
Transformer – Positional Embedding

- suis
- étudiant

http://jalammar.github.io/images/t/transformer_positional_encoding_vectors.png
Positional Embeddings

We need to encode positional information (which was implicit in RNNs).

- Learned embeddings for every position.
- Sinusoids of different frequencies:

\[
\begin{align*}
\text{PE}_{(pos,2i)} &= \sin \left( \frac{pos}{10000^{2i/d}} \right) \\
\text{PE}_{(pos,2i+1)} &= \cos \left( \frac{pos}{10000^{2i/d}} \right)
\end{align*}
\]

This choice of functions should allow the model to attend to relative positions, since for any fixed \( k \), \( \text{PE}_{\text{pos}+k} \) is a linear function of \( \text{PE}_{\text{pos}} \), because

\[
\begin{align*}
\text{PE}_{(\text{pos}+k,2i)} &= \sin \left( \frac{(pos+k)}{10000^{2i/d}} \right) \\
&= \sin \left( \frac{pos}{10000^{2i/d}} \right) \cdot \cos \left( \frac{k}{10000^{2i/d}} \right) + \cos \left( \frac{pos}{10000^{2i/d}} \right) \cdot \sin \left( \frac{k}{10000^{2i/d}} \right) \\
&= \text{offset}_{(k,2i)} \cdot \text{PE}_{(pos,2i)} + \text{offset}_{(k,2i+1)} \cdot \text{PE}_{(pos,2i+1)}.
\end{align*}
\]
Positional Embeddings

Sinusoids of different frequencies

In the original description of positional embeddings (the one used on the previous slide), the sines and cosines are interleaved, so for $d = 6$, the positional embeddings would look like:

$$\text{PE}_{\text{pos}} = \left( \sin \left( \frac{\text{pos}}{10000^0} \right), \cos \left( \frac{\text{pos}}{10000^0} \right), \sin \left( \frac{\text{pos}}{10000^{1/3}} \right), \cos \left( \frac{\text{pos}}{10000^{1/3}} \right), \sin \left( \frac{\text{pos}}{10000^{2/3}} \right), \cos \left( \frac{\text{pos}}{10000^{2/3}} \right) \right).$$

However, in practice, most implementations concatenate first all the sines and only then all the cosines:

$$\overline{\text{PE}}_{\text{pos}} = \left( \sin \left( \frac{\text{pos}}{10000^0} \right), \sin \left( \frac{\text{pos}}{10000^{1/3}} \right), \sin \left( \frac{\text{pos}}{10000^{2/3}} \right), \cos \left( \frac{\text{pos}}{10000^0} \right), \cos \left( \frac{\text{pos}}{10000^{1/3}} \right), \cos \left( \frac{\text{pos}}{10000^{2/3}} \right) \right).$$

This is also how we visualize the positional embeddings on the following slides.

Regularization

The network is regularized by:

- dropout of input embeddings,
- dropout of each sub-layer, just before it is added to the residual connection (and then normalized),
- label smoothing.

Default dropout rate and also label smoothing weight is 0.1.

Parallel Execution

Because of the masked attention, training can be performed in parallel.

However, inference is still sequential.
Optimizer

Adam optimizer (with $\beta_2 = 0.98$, smaller than the default value of 0.999) is used during training, with the learning rate decreasing proportionally to inverse square root of the step number.

Warmup

Furthermore, during the first \textit{warmup_steps} updates, the learning rate is increased linearly from zero to its target value.

\[
\text{learning\_rate} = \frac{1}{\sqrt{d_{\text{model}}}} \min \left( \frac{1}{\sqrt{\text{step\_num}}}, \frac{\text{step\_num}}{\text{warmup\_steps}} \cdot \frac{1}{\sqrt{\text{warmup\_steps}}} \right).
\]

In the original paper, 4000 warmup steps were proposed.

Note that the goal of warmup is mostly to prevent divergence early in training; the Pre-LN configuration usually trains well even without warmup.
Table 2: The Transformer achieves better BLEU scores than previous state-of-the-art models on the English-to-German and English-to-French newstest2014 tests at a fraction of the training cost.

Main Takeaway

Generally, Transformer provides more powerful sequence-to-sequence architecture and also sequence element representation architecture than RNNs, but requires substantially more data.

3D Visualization of a Decoder-only Model

On https://bbycroft.net/llm you can find a 3D visualization with the description of the Transformer computation steps of several GPT models. The GPT models are language models (they estimate conditional probability of a word given its previous context), and therefore consist purely of the decoder part of a Transformer (so they do not contain neither an encoder nor encoder-decoder attention; consequently, all their self-attentions are masked).
