Reinforcement Learning

NPFL138, Lecture 12

Reinforcement learning is a machine learning paradigm, different from *supervised* and *unsupervised learning*.

The essence of reinforcement learning is to learn from *interactions* with the environment to maximize a numeric *reward* signal. The learner is not told which actions to take, and the actions may affect not just the immediate reward, but also all following rewards.

GenerativeModels VAE

Multi-armed Bandits

We start by selecting action A_1 , which is the index of the arm to use, and we get a reward of R_1 . We then repeat the process by selecting actions A_2 , A_3 , ...

Let $q_*(a)$ be the real **value** of an action a:

$$q_*(a) = \mathbb{E}[R_t|A_t = a].$$

Denoting $Q_t(a)$ our estimated value of action a at time t (before taking trial t), we would like $Q_t(a)$ to converge to $q_*(a)$. A natural way to estimate $Q_t(a)$ is

 $Q_t(a) \stackrel{ ext{def}}{=} rac{ ext{sum of rewards when action } a ext{ is taken}}{ ext{number of times action } a ext{ was taken}}.$

Following the definition of $Q_t(a)$, we could choose a **greedy** action A_t as

$$A_t \stackrel{ ext{def}}{=} rg\max_a Q_t(a).$$

Exploitation versus Exploration

Choosing a greedy action is **exploitation** of current estimates. We however also need to **explore** the space of actions to improve our estimates.

An ε -greedy method follows the greedy action with probability $1 - \varepsilon$, and chooses a uniformly random action with probability ε .

NAS

ε -greedy Method

GenerativeModels VAE

Markov Decision Process

A Markov decision process (MDP) is a quadruple $(\mathcal{S}, \mathcal{A}, p, \gamma)$, where:

- \mathcal{S} is a set of states.
- \mathcal{A} is a set of actions.
- $p(S_{t+1} = s', R_{t+1} = r | S_t = s, A_t = a)$ is a probability that action $a \in \mathcal{A}$ will lead from state $s \in \mathcal{S}$ to $s' \in \mathcal{S}$, producing a **reward** $r \in \mathbb{R}$,
- $\gamma \in [0,1]$ is a **discount factor** (we always use $\gamma = 1$ and finite episodes in this course).

Let a **return** G_t be $G_t \stackrel{\text{\tiny def}}{=} \sum_{k=0}^{\infty} \gamma^k R_{t+1+k}$. The goal is to optimize $\mathbb{E}[G_0]$.

Episodic and Continuing Tasks

If the agent-environment interaction naturally breaks into independent subsequences, usually called **episodes**, we talk about **episodic tasks**. Each episode then ends in a special **terminal state**, followed by a reset to a starting state (either always the same, or sampled from a distribution of starting states).

In episodic tasks, it is often the case that every episode ends in at most H steps. These **finite-horizon tasks** then can use discount factor $\gamma = 1$, because the return $G \stackrel{\text{def}}{=} \sum_{t=0}^{H} \gamma^t R_{t+1}$ is well defined.

If the agent-environment interaction goes on and on without a limit, we instead talk about **continuing tasks**. In this case, the discount factor γ needs to be sharply smaller than 1.

14/56

A **policy** π computes a distribution of actions in a given state, i.e., $\pi(a|s)$ corresponds to a probability of performing an action a in state s.

We will model a policy using a neural network with parameters $\boldsymbol{\theta}$:

 $\pi(a|s; \boldsymbol{\theta}).$

If the number of actions is finite, we consider the policy to be a categorical distribution and utilize the softmax output activation as in supervised classification.

(State-)Value and Action-Value Functions

Ú_F≩L

To evaluate a quality of a policy, we define value function $v_{\pi}(s)$, or state-value function, as

$$egin{aligned} v_{\pi}(s) \stackrel{ ext{def}}{=} \mathbb{E}_{\pi} \left[G_t | S_t = s
ight] = \mathbb{E}_{\pi} \left[\sum_{k=0}^{\infty} \gamma^k R_{t+k+1} \Big| S_t = s
ight] \ &= \mathbb{E}_{A_t \sim \pi(s)} \mathbb{E}_{S_{t+1}, R_{t+1} \sim p(s, A_t)} \left[R_{t+1} + \gamma \mathbb{E}_{A_{t+1} \sim \pi(S_{t+1})} \mathbb{E}_{S_{t+2}, R_{t+2} \sim p(S_{t+1}, A_{t+1})} \left[R_{t+2} + \dots
ight]
ight] \end{aligned}$$

An action-value function for a policy π is defined analogously as

$$q_{\pi}(s,a) \stackrel{\scriptscriptstyle{ ext{def}}}{=} \mathbb{E}_{\pi}\left[G_t|S_t=s,A_t=a
ight] = \mathbb{E}_{\pi}\left[\sum_{k=0}^{\infty}\gamma^k R_{t+k+1}\Big|S_t=s,A_t=a
ight].$$

The value function and the state-value function can be easily expressed using one another:

$$egin{aligned} v_\pi(s) &= \mathbb{E}_{a \sim \pi}ig[q_\pi(s,a)ig], \ q_\pi(s,a) &= \mathbb{E}_{s',r \sim p}ig[r+\gamma v_\pi(s')ig]. \end{aligned}$$

NPFL138, Lecture 12

RL

REINFORCE

Baseline NAS

GenerativeModels

Optimal Value Functions

Optimal state-value function is defined as

$$v_*(s) \stackrel{ ext{\tiny def}}{=} \max_\pi v_\pi(s),$$

and **optimal action-value function** is defined analogously as

$$q_*(s,a) \stackrel{ ext{\tiny def}}{=} \max_\pi q_\pi(s,a).$$

Any policy π_* with $v_{\pi_*} = v_*$ is called an **optimal policy**. Such policy can be defined as $\pi_*(s) \stackrel{\text{def}}{=} rg\max_a q_*(s, a) = rg\max_a \mathbb{E}[R_{t+1} + \gamma v_*(S_{t+1})|S_t = s, A_t = a]$. When multiple actions maximize $q_*(s, a)$, the optimal policy can stochastically choose any of them.

Existence

In finite-horizon tasks or if $\gamma < 1$, there always exists a unique optimal state-value function, a unique optimal action-value function, and a (not necessarily unique) optimal policy.

Policy Gradient Methods

We train the policy

 $\pi(a|s;oldsymbol{ heta})$

```
by maximizing the expected return v_{\pi}(s).
```

To that account, we need to compute its gradient $\nabla_{\theta} v_{\pi}(s)$.

GenerativeModels VAE

Policy Gradient Theorem

Assume that S and A are finite, $\gamma = 1$, and that maximum episode length H is also finite. Let $\pi(a|s; \theta)$ be a parametrized policy. We denote the initial state distribution as h(s) and the on-policy distribution under π as $\mu(s)$. Let also $J(\theta) \stackrel{\text{def}}{=} \mathbb{E}_{s \sim h} v_{\pi}(s)$.

Then

$$abla_{oldsymbol{ heta}} v_{\pi}(s) \propto \sum_{s' \in \mathcal{S}} P(s
ightarrow \ldots
ightarrow s' | \pi) \sum_{a \in \mathcal{A}} q_{\pi}(s',a)
abla_{oldsymbol{ heta}} \pi(a|s';oldsymbol{ heta})$$

and

$$abla_{oldsymbol{ heta}} J(oldsymbol{ heta}) \propto \sum_{s \in \mathcal{S}} \mu(s) \sum_{a \in \mathcal{A}} q_{\pi}(s,a)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}),$$

where $P(s \to ... \to s' | \pi)$ is the probability of getting to state s' when starting from state s, after any number of 0, 1, ... steps.

Proof of Policy Gradient Theorem

$$\begin{split} \nabla v_{\pi}(s) &= \nabla \Big[\sum_{a} \pi(a|s; \boldsymbol{\theta}) q_{\pi}(s, a) \Big] \\ &= \sum_{a} \Big[q_{\pi}(s, a) \nabla \pi(a|s; \boldsymbol{\theta}) + \pi(a|s; \boldsymbol{\theta}) \nabla q_{\pi}(s, a) \Big] \\ &= \sum_{a} \Big[q_{\pi}(s, a) \nabla \pi(a|s; \boldsymbol{\theta}) + \pi(a|s; \boldsymbol{\theta}) \nabla \big(\sum_{s', r} p(s', r|s, a)(r + v_{\pi}(s')) \big) \Big] \\ &= \sum_{a} \Big[q_{\pi}(s, a) \nabla \pi(a|s; \boldsymbol{\theta}) + \pi(a|s; \boldsymbol{\theta}) \big(\sum_{s'} p(s'|s, a) \nabla v_{\pi}(s') \big) \Big] \end{split}$$

We now expand $v_{\pi}(s')$.

$$=\sum_{a}\left[q_{\pi}(s,a)
abla\pi(a|s;oldsymbol{ heta})+\pi(a|s;oldsymbol{ heta})iggl(\sum_{s'}p(s'|s,a)iggl(\sum_{s''}p(s''|s',a')
abla v_{\pi}(s'')iggr)iggr)iggr)iggr)
ight] \\ \sum_{a'}\left[q_{\pi}(s',a')
abla\pi(a'|s';oldsymbol{ heta})+\pi(a'|s';oldsymbol{ heta})iggl(\sum_{s''}p(s''|s',a')
abla v_{\pi}(s'')iggr)iggr)iggr)iggr)iggr)iggr)iggr)$$

Continuing to expand all $v_{\pi}(s'')$, we obtain the following:

$$abla v_\pi(s) = \sum_{s'\in\mathcal{S}}\sum_{k=0}^H P(s o s' ext{ in } k ext{ steps } |\pi) \sum_{a\in\mathcal{A}} q_\pi(s',a)
abla_{oldsymbol{ heta}} \pi(a|s';oldsymbol{ heta}).$$

NPFL138, Lecture 12 RL

MABandits MDP

REINFORCE

Baseline NAS

Proof of Policy Gradient Theorem

To finish the proof of the first part, it is enough to realize that

$$\sum_{k=0}^{H} P(s
ightarrow s' ext{ in } k ext{ steps } |\pi) \propto P(s
ightarrow \ldots
ightarrow s' |\pi).$$

For the second part, we know that

$$abla_{oldsymbol{ heta}} J(oldsymbol{ heta}) = \mathbb{E}_{s \sim h}
abla_{oldsymbol{ heta}} v_{\pi}(s) \propto \mathbb{E}_{s \sim h} \sum_{s' \in \mathcal{S}} P(s
ightarrow \ldots
ightarrow s'|\pi) \sum_{a \in \mathcal{A}} q_{\pi}(s',a)
abla_{oldsymbol{ heta}} \pi(a|s';oldsymbol{ heta}),$$

therefore using the fact that $\mu(s') = \mathbb{E}_{s \sim h} P(s
ightarrow \ldots
ightarrow s' | \pi)$ we get

$$abla_{oldsymbol{ heta}} J(oldsymbol{ heta}) \propto \sum_{s \in \mathcal{S}} \mu(s) \sum_{a \in \mathcal{A}} q_{\pi}(s,a)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}).$$

Finally, note that the theorem can be proven with infinite S and A; and also for infinite episodes when discount factor $\gamma < 1$.

REINFORCE Algorithm

The REINFORCE algorithm (Williams, 1992) uses directly the policy gradient theorem, minimizing $-J(\theta) \stackrel{\text{\tiny def}}{=} -\mathbb{E}_{s \sim h} v_{\pi}(s)$. The loss gradient is then

$$abla_{oldsymbol{ heta}} - J(oldsymbol{ heta}) \propto -\sum_{s\in\mathcal{S}} \mu(s) \sum_{a\in\mathcal{A}} q_{\pi}(s,a)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}) = -\mathbb{E}_{s\sim\mu} \sum_{a\in\mathcal{A}} q_{\pi}(s,a)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}).$$

However, the sum over all actions is problematic. Instead, we rewrite it to an expectation which we can estimate by sampling:

$$abla_{oldsymbol{ heta}} - J(oldsymbol{ heta}) \propto \mathbb{E}_{s \sim \mu} \mathbb{E}_{a \sim \pi} q_{\pi}(s, a)
abla_{oldsymbol{ heta}} - \log \pi(a|s; oldsymbol{ heta}),$$

where we used the fact that

RL

$$abla_{oldsymbol{ heta}} \log \pi(a|s;oldsymbol{ heta}) = rac{1}{\pi(a|s;oldsymbol{ heta})}
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}).$$

NPFL138, Lecture 12

MABandits MDP

REINFORCE

Baseline NAS

RLWhatNext GenerativeModels

VAE 21/56

REINFORCE Algorithm

REINFORCE therefore minimizes the loss $-J(\boldsymbol{\theta})$ with gradient

$$\mathbb{E}_{s\sim\mu}\mathbb{E}_{a\sim\pi}q_{\pi}(s,a)
abla_{oldsymbol{ heta}}-\log\pi(a|s;oldsymbol{ heta}),$$

where we estimate the $q_{\pi}(s, a)$ by a single sample.

Note that the loss is just a weighted variant of negative log-likelihood (NLL), where the sampled actions play a role of gold labels and are weighted according to their return.

REINFORCE: Monte-Carlo Policy-Gradient Control (episodic) for π_*

```
Input: a differentiable policy parameterization \pi(a|s, \theta)

Algorithm parameter: step size \alpha > 0

Initialize policy parameter \theta \in \mathbb{R}^{d'} (e.g., to 0)

Loop forever (for each episode):

Generate an episode S_0, A_0, R_1, \dots, S_{T-1}, A_{T-1}, R_T, following \pi(\cdot|\cdot, \theta)

Loop for each step of the episode t = 0, 1, \dots, T - 1:

G \leftarrow \sum_{k=t+1}^T \gamma^{k-t-1} R_k

\theta \leftarrow \theta + \alpha G \nabla \ln \pi(A_t|S_t, \theta)
(G<sub>t</sub>)
```

REINFORCE with Baseline

The returns can be arbitrary – better-than-average and worse-than-average returns cannot be recognized from the absolute value of the return.

Hopefully, we can generalize the policy gradient theorem using a baseline b(s) to

$$abla_{oldsymbol{ heta}} J(oldsymbol{ heta}) \propto \sum_{s \in \mathcal{S}} \mu(s) \sum_{a \in \mathcal{A}} ig(q_{\pi}(s,a) - b(s) ig)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}).$$

The baseline b(s) can be a function or even a random variable, as long as it does not depend on a, because

$$\sum_a b(s)
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}) = b(s) \sum_a
abla_{oldsymbol{ heta}} \pi(a|s;oldsymbol{ heta}) = b(s)
abla_{oldsymbol{ heta}} \sum_a \pi(a|s;oldsymbol{ heta}) = b(s)
abla_{oldsymbol{ heta}} 1 = 0.$$

NPFL138, Lecture 12

RL

Baseline NAS

REINFORCE with Baseline

A good choice for b(s) is $v_{\pi}(s)$, which can be shown to minimize the variance of the gradient estimator. Such baseline reminds centering of the returns, given that

$$v_{\pi}(s) = \mathbb{E}_{a \sim \pi} q_{\pi}(s,a).$$

Then, better-than-average returns are positive and worse-than-average returns are negative. The resulting $q_{\pi}(s, a) - v_{\pi}(s)$ function is also called the **advantage** function

$$a_\pi(s,a) \stackrel{ ext{\tiny def}}{=} q_\pi(s,a) - v_\pi(s).$$

Of course, the $v_{\pi}(s)$ baseline can be only approximated. If neural networks are used to estimate $\pi(a|s; \theta)$, then some part of the network is usually shared between the policy and value function estimation, which is trained using mean square error of the predicted and observed return.

REINFORCE with Baseline (episodic), for estimating $\pi_{\theta} \approx \pi_*$

Input: a differentiable policy parameterization $\pi(a|s, \theta)$ Input: a differentiable state-value function parameterization $\hat{v}(s, \mathbf{w})$ Algorithm parameters: step sizes $\alpha^{\theta} > 0, \ \alpha^{\mathbf{w}} > 0$ Initialize policy parameter $\boldsymbol{\theta} \in \mathbb{R}^{d'}$ and state-value weights $\mathbf{w} \in \mathbb{R}^{d}$ (e.g., to **0**) Loop forever (for each episode): Generate an episode $S_0, A_0, R_1, \ldots, S_{T-1}, A_{T-1}, R_T$, following $\pi(\cdot | \cdot, \theta)$ Loop for each step of the episode $t = 0, 1, \ldots, T - 1$: $G \leftarrow \sum_{k=t+1}^{T} \gamma^{k-t-1} R_k$ (G_{t}) $\delta \leftarrow G - \hat{v}(S_t, \mathbf{w})$ $\mathbf{w} \leftarrow \mathbf{w} + \alpha^{\mathbf{w}} \delta \nabla \hat{v}(S_t, \mathbf{w})$ $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \alpha^{\boldsymbol{\theta}} \delta \nabla \ln \pi (A_t | S_t, \boldsymbol{\theta})$

EfficientNet Search

Ú F_ÁL

EfficientNet changes the search in three ways.

• Computational requirements are part of the return. Notably, the goal is to find an architecture m maximizing

$$ext{DevelopmentAccuracy}(m) \cdot \left(rac{ ext{TargetFLOPS}=400 ext{M}}{ ext{FLOPS}(m)}
ight)^{0.07},$$

where the constant 0.07 balances the accuracy and FLOPS (the constant comes from an empirical observation that doubling the FLOPS brings about 5% relative accuracy gain, and $1.05 = 2^{\beta}$ gives $\beta \approx 0.0704$).

- It uses a different search space allowing to control kernel sizes and channels in different parts of the architecture (compared to using the same cell everywhere as in NASNet).
- Training directly on ImageNet, but only for 5 epochs.

In total, 8k model architectures are sampled, and PPO algorithm is used instead of the REINFORCE with baseline.

EfficientNet Search

The overall architecture consists of 7 blocks, each described by 6 parameters – 42 parameters in total, compared to 50 parameters of Convolutional kernel size KernelSize: 3x3, 5x5. the NASNet search space.

- Convolutional ops *ConvOp*: regular conv (conv), depthwise conv (dconv), and mobile inverted bottleneck conv [29].
- Squeeze-and-excitation [13] ratio SERatio: 0, 0.25.
- Skip ops *SkipOp*: pooling, identity residual, or no skip.
- Output filter size F_i .
- Number of layers per block N_i .

Generative models are given a set of realizations of a random variable ${\bf x}$ and their goal is to estimate $P({m x})$.

Usually the goal is to be able to sample from $P(\mathbf{x})$, but sometimes an explicit calculation of $P(\mathbf{x})$ is also possible.

MDP

RLWhatNext GenerativeModels

Deep Generative Models

Figure 1 of "Auto-Encoding Variational Bayes", https://arxiv.org/abs/1312.6114

One possible approach to estimate $P(\mathbf{x})$ is to assume that the random variable \mathbf{x} depends on a **latent variable z**:

$$P(oldsymbol{x}) = \sum_{oldsymbol{z}} P(oldsymbol{z}) P(oldsymbol{x} | oldsymbol{z}) = \mathbb{E}_{oldsymbol{z} \sim P(oldsymbol{z})} P(oldsymbol{x} | oldsymbol{z}).$$

We use neural networks to estimate the conditional probability $P_{\theta}(\boldsymbol{x}|\boldsymbol{z})$.

AutoEncoders

- Autoencoders are useful for unsupervised feature extraction, especially when performing input compression (i.e., when the dimensionality of the latent space z is smaller than the dimensionality of the input).
- When $oldsymbol{x}+oldsymbol{arepsilon}$ is used as input, autoencoders can perform denoising.
- However, the latent space z does not need to be fully covered, so a randomly chosen z does not need to produce a valid x.

AutoEncoders

encoded data can be decoded without loss if the autoencoder has enough degrees of freedom

without explicit regularisation, some points of the latent space

are "meaningless" once decoded

Variational AutoEncoders

We assume $P(\mathbf{z})$ is fixed and independent on \mathbf{x} .

We approximate $P(\boldsymbol{x}|\boldsymbol{z})$ using $P_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$. However, in order to train an autoencoder, we need to know the posterior $P_{\theta}(\boldsymbol{z}|\boldsymbol{x})$, which is usually intractable.

We therefore approximate $P_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x})$ by a trainable $Q_{\varphi}(\boldsymbol{z}|\boldsymbol{x})$.

Jensen's Inequality

To derive a loss for training variational autoencoders, we first formulate the Jensen's inequality. Recall that convex functions by definition fulfil that for $\boldsymbol{u}, \boldsymbol{v}$ and real $0 \le t \le 1$,

$$f(toldsymbol{u}+(1-t)oldsymbol{v})\leq tf(oldsymbol{u})+(1-t)f(oldsymbol{v}).$$

The **Jensen's inequality** generalizes the above property to any *convex* combination of points: if we have $u_i \in \mathbb{R}^D$ and $_{https://upload.wikimedia.org/wikipedia/commons/c/c7/ConvexFunction.svg}$ weights $w_i \in \mathbb{R}^+$ such that $\sum_i w_i = 1$, it holds that

$$fig(\sum_i w_i oldsymbol{u}_iig) \leq \sum_i w_i fig(oldsymbol{u}_iig).$$

The Jensen's inequality can be formulated also for probability distributions (whose expectation can be considered an infinite convex combination):

$$fig(\mathbb{E}[\mathbf{u}]ig) \leq \mathbb{E}_{\mathbf{u}}ig[f(\mathbf{u})ig].$$

VAE – Loss Function Derivation

Our goal will be to maximize the log-likelihood as usual, but we need to express it using the latent variable z:

$$\log P_{oldsymbol{ heta}}(oldsymbol{x}) = \log \mathbb{E}_{P(oldsymbol{z})}ig[P_{oldsymbol{ heta}}(oldsymbol{x}|oldsymbol{z})ig].$$

However, approximating the expectation using a single sample has monstrous variance, because for most z, $P_{\theta}(x|z)$ will be nearly zero.

We therefore turn to our *encoder*, which is able for a given $m{x}$ to generate "its" $m{z}$:

$$egin{aligned} \log P_{m{ heta}}(m{x}) &= \log \mathbb{E}_{P(m{z})}ig[P_{m{ heta}}(m{x}|m{z})ig] \ &= \log \mathbb{E}_{Q_{arphi}(m{z}|m{x})}igg[P_{m{ heta}}(m{x}|m{z})\cdotrac{P(m{z})}{Q_{arphi}(m{z}|m{x})}igg] \ &\geq \mathbb{E}_{Q_{arphi}(m{z}|m{x})}igg[\log P_{m{ heta}}(m{x}|m{z}) + \lograc{P(m{z})}{Q_{arphi}(m{z}|m{x})}igg] \ &= \mathbb{E}_{Q_{arphi}(m{z}|m{x})}igg[\log P_{m{ heta}}(m{x}|m{z})igg] - D_{\mathrm{KL}}igg(Q_{arphi}(m{z}|m{x})\|P(m{z})igg). \end{aligned}$$

NPFL138, Lecture 12

RL

Baseline

VAE – Variational (or Evidence) Lower Bound

The resulting variational lower bound or evidence lower bound (ELBO), denoted $\mathcal{L}(\theta, \varphi; \mathbf{x})$, can be also defined explicitly as:

$$\mathcal{L}(oldsymbol{ heta},oldsymbol{arphi};\mathbf{x}) = \log P_{oldsymbol{ heta}}(oldsymbol{x}) - D_{ ext{KL}}ig(Q_{oldsymbol{arphi}}(oldsymbol{z}|oldsymbol{x})ig\|P_{oldsymbol{ heta}}(oldsymbol{z}|oldsymbol{x})ig).$$

Because KL-divergence is nonnegative, $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\varphi}; \mathbf{x}) \leq \log P_{\boldsymbol{\theta}}(\boldsymbol{x}).$

By using simple properties of conditional and joint probability, we get that

$$egin{aligned} \mathcal{L}(oldsymbol{ heta},oldsymbol{arphi};\mathbf{x}) &= \mathbb{E}_{Q_arphi(oldsymbol{z}|oldsymbol{x})}igg[\log P_{oldsymbol{ heta}}(oldsymbol{x}) + \log P_{oldsymbol{ heta}}(oldsymbol{z}|oldsymbol{x})igg] \ &= \mathbb{E}_{Q_arphi(oldsymbol{z}|oldsymbol{x})}igg[\log P_{oldsymbol{ heta}}(oldsymbol{x},oldsymbol{z}) - \log Q_arphi(oldsymbol{z}|oldsymbol{x})igg] \ &= \mathbb{E}_{Q_arphi(oldsymbol{z}|oldsymbol{x})}igg[\log P_{oldsymbol{ heta}}(oldsymbol{x}|oldsymbol{z}) + \log P(oldsymbol{z}) - \log Q_arphi(oldsymbol{z}|oldsymbol{x})igg] \ &= \mathbb{E}_{Q_arphi(oldsymbol{z}|oldsymbol{x})}igg[\log P_{oldsymbol{ heta}}(oldsymbol{x}|oldsymbol{z}) + \log P(oldsymbol{z}) - \log Q_arphi(oldsymbol{z}|oldsymbol{x})igg] \ &= \mathbb{E}_{Q_arphi(oldsymbol{z}|oldsymbol{x})}igg[\log P_{oldsymbol{ heta}}(oldsymbol{x}|oldsymbol{z})igg] - D_{ ext{KL}}igg(Q_arphi(oldsymbol{z}|oldsymbol{x}))iggl]. \end{aligned}$$

GenerativeModels

$$-\mathcal{L}(oldsymbol{ heta},oldsymbol{arphi};\mathbf{x}) = \mathbb{E}_{Q_{oldsymbol{arphi}}(oldsymbol{z}|oldsymbol{x})}igg[-\log P_{oldsymbol{ heta}}(oldsymbol{x}|oldsymbol{z})igg] + D_{ ext{KL}}igl(Q_{oldsymbol{arphi}}(oldsymbol{z}|oldsymbol{x})\|P(oldsymbol{z})igr)$$

- We train a VAE by minimizing the $-\mathcal{L}(\boldsymbol{ heta}, \boldsymbol{arphi}; \mathbf{x})$.
- The $\mathbb{E}_{Q_{\varphi}(\boldsymbol{z}|\boldsymbol{x})}$ is estimated using a single sample.
- The distribution $Q_{\varphi}(\boldsymbol{z}|\boldsymbol{x})$ is parametrized as a normal distribution $\mathcal{N}(\boldsymbol{z}|\boldsymbol{\mu}, \boldsymbol{\sigma}^2)$, with the model predicting $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ given \boldsymbol{x} .
 - In order for σ to be positive, we can use exp activation function (so that the network predicts $\log \sigma$ before the activation), or for example a softplus activation function.
 - $^{\circ}$ The normal distribution is used, because we can sample from it efficiently, we can backpropagate through it and we can compute D_{KL} analytically; furthermore, if we decide to parametrize $Q_{\varphi}(\boldsymbol{z}|\boldsymbol{x})$ using mean and variance, the maximum entropy principle suggests we should use the normal distribution.
- We use a prior $P(\boldsymbol{z}) = \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}).$

Variational AutoEncoders Training

Note that the loss has 2 intuitive components:

- reconstruction loss starting with \boldsymbol{x} , passing though Q_{φ} , sampling \boldsymbol{z} and then passing through $P_{\boldsymbol{\theta}}$ should arrive back at \boldsymbol{x} ;
- latent loss over all *x*, the distribution of Q_φ(*z*|*x*) should be as close as possible to the prior P(*z*) = N(0, *I*), which is independent on *x*.

Variational AutoEncoders – Reparametrization Trick

49/56

In order to backpropagate through $m{z} \sim Q_{m{arphi}}(m{z}|m{x})$, note that if

 $oldsymbol{z} \sim \mathcal{N}(oldsymbol{\mu},oldsymbol{\sigma}^2),$

we can write \boldsymbol{z} as

$$oldsymbol{z} \sim oldsymbol{\mu} + oldsymbol{\sigma} \odot \mathcal{N}(oldsymbol{0},oldsymbol{I}).$$

Such formulation then allows differentiating z with respect to μ and σ and is called a **reparametrization trick** (Kingma and Welling, 2013).

Variational AutoEncoders – Reparametrization Trick

no problem for backpropagation

---- backpropagation is not possible due to sampling

sampling without reparametrisation trick

sampling with reparametrisation trick
